Abstract

We analyse metapopulation dynamics in terms of an individual-based, stochastic model of a finite metapopulation. We suggest a new approach, using the number of patches in the population as a large parameter. This approach does not require that the number of individuals per patch is large, neither is it necessary to assume a time-scale separation between local population dynamics and migration. Our approach makes it possible to accurately describe the dynamics of metapopulations consisting of many small patches. We focus on metapopulations on the brink of extinction. We estimate the time to extinction and describe the most likely path to extinction. We find that the logarithm of the time to extinction is proportional to the product of two vectors, a vector characterising the distribution of patch population sizes in the quasi-steady state, and a vector – related to Fisher’s reproduction vector – that quantifies the sensitivity of the quasi-steady state distribution to demographic fluctuations. We compare our analytical results to stochastic simulations of the model, and discuss the range of validity of the analytical expressions. By identifying fast and slow degrees of freedom in the metapopulation dynamics, we show that the dynamics of large metapopulations close to extinction is approximately described by a deterministic equation originally proposed by Levins (1969). We were able to compute the rates in Levins’ equation in terms of the parameters of our stochastic, individual-based model. It turns out, however, that the interpretation of the dynamical variable depends strongly on the intrinsic growth rate and carrying capacity of the patches. Only when the growth rate and the carrying capacity are large does the slow variable correspond to the number of patches, as envisaged by Levins. Last but not least, we discuss how our findings relate to other, widely used metapopulation models.

Keywords: Metapopulations, stochastic dynamics, extinction, migration

1. Introduction

The habitats of animal populations are often geographically divided into many small patches, either because of human interference or because natural habitats are patchy. Understanding the dynamics of such populations is a problem of great theoretical and practical interest. Isolated small patches are often extinction prone, for example because of inbreeding in combination with demographic and environmental stochasticity (Hanski, 1999). When the patches are connected into a network by migration, local populations may still be prone to extinction, but the whole population may persist because empty patches are re-colonised by migrants from surrounding occupied patches. Moreover, when the migration rate is sufficiently large, local populations can be stabilised by an inflow of immigrants (the rescue effect). Given a model of such a population, the main concern is usually to find out how the different parameter values in the model affect the growth and persistence of the metapopulation.

In Levins' model, the metapopulation dynamics is simplified by treating each patch as either occupied or empty (Levins, 1969). The rates of patch colonisation and extinction are expressed as functions of the total fraction of occupied patches in the population. In its simplest form Levins' model describes the time change of the fraction Q of occupied patches:

$$\frac{dQ}{dt} = c Q(1 - Q) - e Q. \quad (1)$$

Here c is the rate of successful colonisation of an empty patch, and e is the rate at which occupied patches turn empty (the rate of patch extinction). How these rates are related to the life-history parameters determining the stochastic, individual-based metapopulation dynamics is not explicitly known. In spatially explicit models the parameters are chosen to be functions of for example the number of occupied neighbouring patches (Hui and Li, 2004; Roy et al., 2008). Eq. (1) is generally motivated by assuming a separation of time scales between colonisation and extinction of patches on the one hand, and the population dynamics within patches on the other hand (Levins, 1969; Hanski and Gyllenberg, 1993; Lande et al., 1998; Etienne, 2002). Many of the mechanisms that can be observed in natural populations (e.g. Allee and rescue effects) can be represented by suitable modifications of Eq. (1), and the qualitative behaviour of such models is well understood (Hanski and Ovaskainen, 2000; Etienne, 2000; Harding and McNamara, 2002; Zhou and Wang, 2004). See also Zhou et al. (2004); Taylor and Hastings (2005), and Martcheva and Bolker (2007).

Models that describe the metapopulation dynamics in terms of the fraction of occupied patches have no explicit connection to the population dynamics within each patch. In other words, it is not apparent how individual births, deaths, and migration events translate into colonisation and extinction rates (Etienne, 2002).

An alternative line of analysis focuses on the population dynamics within a single patch (Drechsler and Wissel, 1997; Lopez and Pfister, 2001; Newman et al., 2004). The advantage of this approach is that birth and death processes, emigration, and immigration can be modelled explicitly in terms of the number of individuals in the patch. This makes the model much more immediate in terms of biological processes (such as density dependence and Allee effects), but the rest of the metapopulation is reduced to a background source of immigrants (assumed to be stationary) and is not explicitly modelled.

Several authors have attempted to bridge the gap between detailed local population dynamics and the dynamics at the overall population level. Keeling (2002) estimated rates of colonisation and extinction events in Levins' equation from individual-based simulations. This method rests on the assumption that Eq. (1) is an appropriate description of the metapopulation dynamics.

Higgins (2009) has investigated the extinction risk of metapopulations subject to strong dispersal, that is, in a limit where migration is faster than the local population dynamics within patches. As pointed out above, the converse is commonly assumed in writing Eq. (1). Within his model, Higgins (2009) addressed the question of how the degree of fragmentation of the metapopulation affects its risk of extinction.

Chesson (1981, 1984), Hanski and Gyllenberg (1993), Casagrandi and Gatto (1999, 2002), Nachman (2000), Metz and Gyllenberg (2001) and others have analysed the equilibrium states and possible persistence of metapopulations in models consisting of infinitely many patches with local dynamics coupled via a migration pool (reviewed in Massol et al., 2009). The assumption that there are infinitely many patches is crucial in these studies, as it makes it possible to pose the question under which circumstances the metapopulation persists *ad infinitum*, that is, for which choice of parameters the metapopulation dynamics reaches a non-trivial stable equilibrium. For finite metapopulations, by contrast, there is no stable equilibrium corresponding to persistence (for a review of stochastic extinctions in biological populations, see e.g. Ovaskainen and Meerson, 2010). As is well known, finite populations must eventually become extinct (unless they continue to grow). This fact is referred to as the 'merciless dichotomy of population dynamics' by Jagers (1992). Moreover, it remains unclear how the equations employed in these studies are related to Eq. (1).

In this paper we characterise the dynamics of metapopulations with a large, but finite, number of patches. We derive, from first principles, how the stochastic metapopulation dynamics determines the distribution of individuals over patches. The only critical assumption in our derivation is that the number of patches is large enough. Especially, it is not necessary to assume that the typical number of individuals per patch is large. Neither is it necessary to assume a time-scale separation between local and migration dynamics. We show that our results represent the typical transient of the metapopulation towards a quasi-steady state (if such a state exists).

On the brink of extinction, that is, close to the bifurcation point where an infinite metapopulation ceases to persist, we use a systematic expansion of an exact master equation in powers of N^{-1} (where N is the number of patches) to find the most likely path to extinction, as well as the leading contribution to the time to extinction. In this case (close to the bifurcation) the metapopulation dynamics simplifies considerably: it can be approximated by a simple, one-dimensional dynamics. This fact is a consequence of a general principle (Guckenheimer and Holmes, 1983) stating that a dynamical system close to a bifurcation exhibits a ‘slow mode’: a particular linear combination of the dynamical variables is found to relax slowly, and the remaining degrees of freedom relax much more quickly and may be assumed to be in local equilibria. In other words, when the dynamical system is in a perturbed state, the slow mode evolves towards the equilibrium state on a longer time-scale than the fast variables do. This renders the dynamics effectively one-dimensional. We find the slow mode of the metapopulation dynamics and show how it depends on the properties of the local dynamics (given by the local growth rate and the local carrying capacity). The slow mode determines the stochastic dynamics of finite metapopulations as well as the deterministic dynamics of metapopulations consisting of infinitely many patches. In the latter case we find that the slow mode obeys Eq. (1). We derive how the parameters c and e depend on the parameters determining the life history of the local populations. We show, however, that the variable Q is in general not given by the fraction of occupied patches as envisaged by Levins. But it turns out that Q approaches the fraction of occupied patches in the limit of large carrying capacities and large local growth rates (this is the limit of time-scale separation mentioned above).

In other words, we have derived Levins’ model, Eq. (1), from a stochastic, individual-based model of a finite metapopulation. We find that Eq. (1) is still valid (close to the bifurcation) even when there is no time-scale separation between the local and the migration dynamics. This is the consequence of the existence of a slow mode.

Lande et al. (1998) have suggested an elegant stochastic generalisation of Levins' model, in an attempt to compute how the local patch dynamics affects the properties of the quasi-steady state of the metapopulation (and the average time to extinction of this population). Their main idea is to connect the extinction and colonisation rates in Eq. (1) to local processes. The extinction rate is calculated as the inverse expected time to extinction of a single patch at the carrying capacity (which is determined self-consistently), and colonisation is defined as the rate of a single migrant arriving to an empty patch, seeding a population that grows to the carrying capacity. This scheme is persuasive but not rigorous. The predictions of Lande et al. (1998) have, to our knowledge, never been tested by comparisons to results of simulations of stochastic, individual-based metapopulation models. Therefore it is important that our approach allows us to compute the rates of extinction and colonisation from first principles. In the limit of large patch carrying capacities and close to the bifurcation we obtain expressions (exact in the limit we consider) that are very similar, but not identical, to the relations proposed by Lande et al. (1998).

In summary, we characterise the stochastic dynamics of metapopulations on the brink of extinction. Using an expansion of the exact master equation describing the stochastic dynamics with the number N of patches as a large parameter, we identify a slow mode in the metapopulation dynamics, regardless of whether there is a time-scale separation between local and global dynamics or not. We show under which circumstances widely used metapopulation models provide accurate descriptions of metapopulation dynamics.

The remainder of this paper is organised as follows. In section 2 we describe the individual-based stochastic metapopulation model investigated here. We summarise how our numerical experiments were performed and briefly describe how to represent the metapopulation dynamics in terms of a master equation, and how to expand this equation in powers of N^{-1} . Our results are described in section 3. We first discuss the limit $N \rightarrow \infty$, demonstrate under which circumstances metapopulations persist in this limit, and analyse the metapopulation dynamics. Second, we turn to stochastic fluctuations of finite metapopulations, and summarise our results on fluctuations in the quasi-steady state, the most likely path to extinction as well as the average time to extinction. Section 4 contains our conclusions. Appendices A, B, and C summarise details of our calculations.

2. Methods

In this section we define the stochastic, individual-based metapopulation model that is analysed in this paper. We describe how our numerical experiments are performed and derive a master equation, Eq. (14), that is the starting point for our mathematical analysis of metapopulation dynamics. In general it is not possible to solve this equation in closed form. We demonstrate how an approximate solution can be obtained by expanding the master equation using the number N of patches as a large parameter. In the limit of $N \rightarrow \infty$, the dynamics reduces to a deterministic model. The equilibrium properties of this model were analysed by Casagrandi and Gatto (1999, 2002), and by Nachman (2000).

2.1. Stochastic, individual-based metapopulation model

The model consists of a population distributed amongst N patches, as illustrated in Fig. 1. In each patch, the local population dynamics is a birth-death process with birth rates b_i , and death rates d_i . Here i denotes the population size in a given patch (and $b_0 = d_0 = 0$). To simplify the discussion we assume that the rates are the same for all patches, but more general cases can be treated within the approach described in this paper. In the following we illustrate our results for a particular choice of birth and death rates:

$$b_i = r i \quad \text{birth rate ,} \quad (2)$$

$$d_i = \mu i + (r - \mu)i^2/K \quad \text{death rate .} \quad (3)$$

The parameter r is the birth rate per individual, μ is the density-independent per capita mortality, and K determines the carrying capacity of a single patch. For simplicity, we take $\mu = 1$ hereafter (this corresponds to measuring time in units of the expected life-time of individuals in the absence of density dependence). The parameters occurring in Eqs. (2,3) are listed in Table 1, which summarises the notation used in this article.

In addition to the local population dynamics, the number of individuals in each patch can change because some individuals emigrate from their patch to other patches, or because immigrants arrive from other patches.

Following Hanski and Gyllenberg (1993), the migration process is modelled as follows: individuals emigrate from a patch at rate m_i , where i is the population size in the patch in question ($m_0 = 0$). If the individuals migrate independently and with constant rates, m_i is proportional to i :

$$m_i = m i \quad \text{emigration rate .} \quad (4)$$

More complex migration patterns can be incorporated. If for example individuals moved to avoid overcrowding, the emigration rate would be density dependent.

The emigrants enter a common dispersal pool, containing the migrants from all patches that have not yet reached their target patch. Each migrant stays an exponentially distributed time in the pool, with expected value $1/\eta$, before reaching the target habitat, which is chosen with equal probability among all patches. This process is illustrated in Fig. 1. Migration may fail if the individuals die before reaching the new habitat; this is modelled by the rate ζ of dying during dispersal. In practice, the probability of successful migration depends on the background mortality of the individuals, on the time the migrating individual spends in the dispersal pool, and on additional perils individuals may be exposed to during dispersal (e.g. increased risk of predation due to lack of cover, etc.). In summary, if there are M migrants, $(\eta + \zeta)M$ individuals leave the dispersal pool per unit of time, and the rate of immigration to a given patch is $I = \eta M/N$.

2.2. Numerical experiments

In the direct numerical simulations, the population evolves in the following manner. First, at any given time, the local rates, Eqs. (2-4), sum to a rate of the next locally generated event, Λ_k , for patch k . This rate is simply the sum of the local rates, Eqs. (2-4). If patch k contains i individuals then we have:

$$\Lambda_k = b_i + d_i + m_i. \quad (5)$$

The sum of these rates over all patches, $\Lambda = \sum_k \Lambda_k$, for $k = 1, \dots, N$, yields the rate for the next event occurring in the population. Thus the simulation proceeds by generating an exponentially distributed random number with expected value $1/\Lambda$. Second, at each time step, a patch is chosen with probability Λ_k/Λ . Third, the type of event is chosen randomly: birth with probability b_i/Λ_k , death with probability d_i/Λ_k or emigration with m_i/Λ_k . Fourth, the numerical experiments described below were performed in the limit $\eta \rightarrow \infty$ and for $\zeta = 0$. This means that emigrating individuals are immediately assigned to a randomly chosen patch (possibly the one they come from).

2.3. Master equation

A natural and commonly adopted approach to describe stochastic population dynamics is to derive a master equation (van Kampen, 1981) for the change in time of the probability ρ of observing i_1 individuals in the first patch, i_2 individuals in the second patch, $\dots$, and of observing M individuals in the migrant pool.

Recently this approach was adopted by Meerson and Sasorov (2011) to describe the dynamics of local birth-death processes coupled by nearest-neighbour interactions (diffusion).

In the following we pursue a different approach. Since the local population dynamics is assumed to be the same within all patches, it is sufficient to count the number of patches with a given number of individuals rather than keeping track of the number of individuals in each patch. Let n_j denote the number of patches with j inhabitants at a given time. The state of the population is described by the variables $n_0, n_1, \dots, M$. In the master equation, the time derivative of the probability $\rho(n_0, n_1, \dots, M; t)$ of observing the system in a given state $n_0, n_1, \dots, M$ at time t , is the rate of arriving to a given state from other states, minus the rate of transitions to other states. Thus, we find the master equation for the probability $\rho(n_0, n_1, \dots, M; t)$ by considering all possible transitions between the states of the population, contributing to the change of $\rho(n_0, n_1, \dots, M; t)$.

For example, consider the effect of local births on the probability of finding the system in a given, ‘focal’ state $n_0, n_1, \dots, M$ at time t . A birth event in a patch with j individuals corresponds to the transition $n_j \rightarrow n_j - 1$ and $n_{j+1} \rightarrow n_{j+1} + 1$. Thus, $d\rho/dt$ has the contribution

$$-b_j n_j \rho(n_0, n_1, \dots, M; t) \quad (6)$$

from births in the focal state. This contribution is negative since any such birth in the focal state moves the system away from this state. In order to obtain the positive contributions to $d\rho/dt$, we calculate the rate of arriving to the focal state by a birth in a different state:

$$b_j(n_j + 1) \rho(\dots, n_j + 1, n_{j+1} - 1, \dots) \quad (7)$$

A compact way of writing these contributions is in terms of the raising and lowering operators $\mathbb{E}_j^\pm$, defined by their effects on a function g (van Kampen, 1981):

$$\begin{aligned} \mathbb{E}_j^+ g(\dots, n_j, \dots) &= g(\dots, n_j + 1, \dots), \\ \mathbb{E}_j^- g(\dots, n_j, \dots) &= g(\dots, n_j - 1, \dots). \end{aligned} \quad (8)$$

In our example, the total contribution to $d\rho/dt$ from birth events can thus be written as

$$\sum_{j=0}^{\infty} (\mathbb{E}_j^+ \mathbb{E}_{j+1}^- - 1) b_j n_j \rho. \quad (9)$$

Adding up the contributions due to death, emigration, and immigration we find:

$$\begin{aligned}
\frac{d\rho}{dt} = & \sum_{j=0}^{\infty} (\mathbb{E}_j^+ \mathbb{E}_{j+1}^- - 1) b_j n_j \rho \\
& + \sum_{j=0}^{\infty} (\mathbb{E}_j^+ \mathbb{E}_{j-1}^- - 1) d_j n_j \rho + \sum_{j=0}^{\infty} (\mathbb{E}_j^+ \mathbb{E}_{j-1}^- \mathbb{E}_M^- - 1) m_j n_j \rho \\
& + \sum_{j=0}^{\infty} (\mathbb{E}_j^+ \mathbb{E}_{j+1}^- \mathbb{E}_M^+ - 1) \eta M \frac{n_j}{N} \rho + (\mathbb{E}_M^+ - 1) \zeta M \rho. \tag{10}
\end{aligned}$$

To simplify the discussion we assume that migration is instantaneous, this corresponds to taking the limit $\eta \rightarrow \infty$ and $\zeta = 0$. In this limit, the immigration rate to a patch is given by:

$$I = \frac{1}{N} \sum_{j=0}^{\infty} m_j n_j, \tag{11}$$

and the corresponding master equation takes the form:

$$\begin{aligned}
\frac{d\rho}{dt} = & \sum_{j=0}^{\infty} (\mathbb{E}_j^+ \mathbb{E}_{j+1}^- - 1) b_j n_j \rho + \sum_{j=0}^{\infty} (\mathbb{E}_j^+ \mathbb{E}_{j-1}^- - 1) d_j n_j \rho \\
& + \frac{1}{N} \sum_{i=1}^{\infty} \sum_{j=0}^{\infty} \mathbb{E}_{i-1}^- \mathbb{E}_i^+ \mathbb{E}_j^+ \mathbb{E}_{j+1}^- m_i n_i (n_j - \delta_{ij} + \delta_{i-1,j}) \rho - \sum_{i=1}^{\infty} m_i n_i \rho. \tag{12}
\end{aligned}$$

The last two terms on the right-hand side of Eq. (12) describe instantaneous migration where $M = 0$. The terms involving Kronecker δ -symbols (see Table 1) on the right-hand side of Eq. (12) arise from enforcing that, for the migration of an individual, emigration must precede immigration. These terms are of higher order in N^{-1} .

The number of patches is given by $N = \sum_{j=0}^{\infty} n_j$. The following discussion is simplified by making this constraint explicit in the master equation (12). This is achieved by considering n_0 , the number of empty patches, to be a function of $n_1, n_2, \dots$:

$$n_0 = N - \sum_{j=1}^{\infty} n_j. \tag{13}$$

Using Eq. (13) we find the following master equation:

$$\begin{aligned}
\frac{d\rho(\mathbf{n}, t)}{dt} = & \sum_{j=1}^{\infty} (\mathbb{E}_j^+ \mathbb{E}_{j+1}^- - 1) b_j n_j \rho(\mathbf{n}, t) + \sum_{j=1}^{\infty} (\mathbb{E}_j^+ \mathbb{E}_{j-1}^- - 1) d_j n_j \rho(\mathbf{n}, t) \\
& + \frac{1}{N} \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} (\mathbb{E}_{i-1}^- \mathbb{E}_i^+ \mathbb{E}_j^+ \mathbb{E}_{j+1}^- - 1) m_i n_i (n_j - \delta_{ij} + \delta_{i-1j}) \rho(\mathbf{n}, t) \\
& + \sum_{i=1}^{\infty} (\mathbb{E}_{i-1}^- \mathbb{E}_i^+ \mathbb{E}_1^- - 1) m_i n_i \left(1 - \frac{1}{N} \sum_{k=1}^{\infty} n_k + \delta_{i1}\right) \rho(\mathbf{n}, t) - \sum_{i=1}^{\infty} m_i n_i \rho. \quad (14)
\end{aligned}$$

Here the components n_j of the vector $\mathbf{n} = (n_1, n_2, \dots)^\top$ denote the number of patches with $j \geq 1$ individuals, and $\mathbb{E}_0^\pm \equiv 1$. Eq. (14) describes the stochastic population dynamics of the metapopulation model considered here.

In the next section we describe the approximate method of solving Eq. (14) adopted in the following. It corresponds to a systematic expansion of the master equation, using the number N of patches in the population as a large parameter. This approach does not require that the number of individuals per patch is large, neither is it necessary to assume a time-scale separation between local population dynamics and migration. Our approach makes it possible to accurately describe the dynamics of metapopulations consisting of many small patches. In the limit of infinitely many patches, to lowest order in the expansion, a deterministic metapopulation dynamics is obtained. Stochastic fluctuations in metapopulations with a large but finite number of patches are described by the leading order of the expansion.

2.4. Expansion of the master equation

When N is large we expect that the probability ρ of observing a given distribution of $\mathbf{n}$ changes only little when patches change in population size. It is important to emphasise that no assumption is made concerning the size of the changes to the population size of any single habitat. It is merely assumed that there are sufficiently many patches that they form a statistical ensemble. In this case it is perfectly possible to have big jumps in the population sizes of individual patches in the model without violating the assumption that the distribution of $\mathbf{n}$ is smooth, and to allow the local population dynamics to depend sensitively on the local patch population size when there are few individuals in the patch — modelling for example the effect of abundance on mating success (Sæther et al., 2004; Melbourne and Hastings, 2008).

It is convenient to express the components of the vector $\mathbf{n}$ in terms of the scaled frequencies $f_j = n_j/N$. The probability $\tilde{\rho}$ of observing $f_1, f_2, \dots$ is related to the probability ρ by

$$\tilde{\rho}(\mathbf{f}; t) = \rho(N\mathbf{f}; t). \quad (15)$$

In contrast to the distribution of n_j , the distribution of f_j is expected to become approximately independent of N for a large number of patches. A change of a single count n_j leads only to a change of $1/N$ in f_j . Since the probability $\tilde{\rho}$ is an approximately continuous function of f_j in the limit of large values of N , we seek an approximate solution of Eq. (14) by expanding this equation in powers of N^{-1} .

In the limit of $N \rightarrow \infty$ we expect that stochastic fluctuations are negligible, so that the metapopulation dynamics becomes deterministic. It takes the form of a kinetic equation for $\mathbf{f}$:

$$\frac{d\mathbf{f}}{dt} = \mathbf{v}(\mathbf{f}). \quad (16)$$

The right-hand side of this equation, $\mathbf{v}(\mathbf{f})$, depends upon the details of the model analysed. For the model described in Section 2.1, the form of $\mathbf{v}(\mathbf{f})$ is given in Eq. (18). In the limit of $N \rightarrow \infty$, the question whether or not the metapopulation may persist is answered by finding the steady states $\mathbf{f}^*$ of the system (16), given by $\mathbf{v}(\mathbf{f}^*) = \mathbf{0}$. Persistence corresponds to the existence of a stable steady state with positive components $f_j^* > 0$ for some values of j . If, by contrast, the only stable steady state is $\mathbf{f}^* = \mathbf{0}$, then the metapopulation will definitely become extinct. The time to extinction is determined by Eq. (16), and by the initial conditions.

For large (but finite) values of N the metapopulation fluctuates around the stable steady states $\mathbf{f}^*$ of Eq. (16). These fluctuations can be described by expanding the master equation (14) to leading order in N^{-1} . The stochastic fluctuations are expected to be small when N is large, but they are crucial to the metapopulation dynamics as mentioned in the Introduction. When the number of patches is finite, the metapopulation must eventually become extinct (the state $\mathbf{f} = \mathbf{0}$ is the only absorbing state of the master equation). When N is large, the time to extinction from a stable steady state of the deterministic dynamics is expected to be large. By analogy with standard large-deviation analysis, we expect that the time to extinction increases exponentially with increasing N , giving rise to a long-lived quasi-steady state. Below we analyse its properties, and estimate the time to extinction of the metapopulation. Our results are consistent with the above expectation, and we show that the time to extinction depends sensitively on the parameters of the model (r , K , m , and N).

2.4.1. Deterministic dynamics in the limit of $N \rightarrow \infty$

To simplify the notation, we drop the tilde in Eq. (15) so that $\rho(\mathbf{f}, t)$ is the probability of observing, at time t , a fraction f_1 of patches with one individual, a fraction f_2 of patches with two individuals, and so forth. In deriving the expansion of the master equation (14) we use the approach described by van Kampen (1981). Assuming that ρ is a smooth function of $\mathbf{f}$, the action of the raising and lowering operators, Eq. (8), can be written as

$$\mathbb{E}_j^\pm = \exp(\pm N^{-1} \partial_{f_j}). \quad (17)$$

The master equation (14) is expanded as follows. We replace n_j by $N f_j$ in Eq. (14), insert Eq. (17), and expand in powers of N^{-1} . Keeping only the lowest order in N^{-1} , we arrive at an equation for ρ that corresponds to deterministic dynamics of the form (16). We find that the components of $\mathbf{v}(\mathbf{f})$ are given by:

$$\begin{aligned} v_j(\mathbf{f}) &= (b_{j-1} + I) f_{j-1} + (d_{j+1} + m_{j+1}) f_{j+1} \\ &\quad - (b_j + I + d_j + m_j) f_j \quad \text{for } j > 1, \\ v_1(\mathbf{f}) &= I(1 - \sum_{k=1}^{\infty} f_k) + (d_2 + m_2) f_2 - (b_1 + I + d_1 + m_1) f_1. \end{aligned} \quad (18)$$

Here $I = \sum_{k=1}^{\infty} m_k f_k$ is the rate of immigration into a given patch, corresponding to Eq. (11). Since I depends upon $\mathbf{f}$, the deterministic dynamics (16,18) is nonlinear. We note that Eqs. (16,18) correspond to the metapopulation model suggested by Casagrandi and Gatto (1999) and Nachman (2000). Here we have derived it by a systematic expansion of the exact master equation in powers of N^{-1} where N is the number of patches. Our derivation emphasises the fact that Eqs. (16,18) approximate the metapopulation dynamics by a deterministic equation. This approximation improves as N becomes larger, and becomes exact as $N \rightarrow \infty$. Arrigoni (2003) has shown that this limit holds under quite general assumptions for the underlying stochastic model, namely that the time-evolution of the probability measure over the states of the model converges to the deterministic time evolution as $N \rightarrow \infty$. Casagrandi and Gatto (1999), Nachman (2000), and others have studied how the stability of the steady states of the deterministic dynamics depends upon the parameters of the model. However, Eqs. (16,18) cannot be used to determine how stochastic population dynamics affects metapopulation persistence. In order to take the stochastic fluctuations into account, it is necessary to consider the next order in $1/N$.

2.4.2. Quasi-steady state distribution at finite but large values of N

Consider a stable steady state of the metapopulation in the limit of infinitely many patches, that is, a stable steady state $\mathbf{f}^*$ of the deterministic dynamics (16).

Metapopulations consisting of a finite number N of patches exhibit random fluctuations caused by the random sequence of birth-, death-, and migration events. When the number of patches is large, these fluctuations are expected to be small, and the components f_j of the vector $\mathbf{f}$ are expected to fluctuate closely around those of the stable steady state $\mathbf{f}^*$. If the fluctuations around $\mathbf{f}^*$ are small, the metapopulation may persist for a very long time (but extinction of this finite metapopulation is certain, as explained above.). This situation is commonly referred to as a ‘quasi-stable’ steady state. We analyse its properties by expanding the master equation to leading order in N^{-1} , using a standard method that is referred to as ‘WKB analysis’ (Wilkinson et al., 2007), as the ‘eikonal approximation’ (Dykman et al., 1994), or as the ‘large-deviation principle’ in the mathematical literature (Freidlin and Wentzell, 1984).

We briefly outline this method in the remainder of this subsection. For a comprehensive description, the reader is referred to Altland and Simons (2010), Elgart and Kamenev (2004), and Dykman et al. (1994). The method has been successfully used to describe fluctuations in finite biological populations, describing for example the spreading of epidemics (Dykman et al., 2008) or the risk of extinction of biological populations (see Ovaskainen and Meerson (2010) for a review).

In the quasi-steady state we expect $d\rho/dt \approx 0$ and seek a solution of the master equation of the form

$$\rho(\mathbf{f}) \approx \exp[-NS(\mathbf{f}) + \text{higher orders in } N^{-1}]. \quad (19)$$

The function $S(\mathbf{f})$ is commonly referred to as the ‘action’. It not only depends upon $\mathbf{f}$, but also on the parameters of the problem (r , K , and m in our case). This dependence is not made explicit in Eq. (19). In the limit of a large number of patches, this function determines the form of the probability distribution $\rho(\mathbf{f})$ in the quasi-steady state, and its sensitive dependence upon the parameters r , K , and m .

As mentioned above, $\rho(\mathbf{f})$ is expected to be strongly peaked at $\mathbf{f}^*$ in the limit of large values of N . In other words, the quasi-steady state distribution concentrates on the deterministic fixed point $\mathbf{f}^*$ as the number of patches tends to infinity. It is therefore convenient to define the action function such that $S(\mathbf{f}^*) = 0$. When the number of patches is large, we expect the distribution $\rho(\mathbf{f})$ to be Gaussian in the

vicinity of the steady state. Correspondingly, $S(\mathbf{f})$ is expected to be approximated by a quadratic function of $\delta\mathbf{f} = \mathbf{f} - \mathbf{f}^*$. By contrast, non-Gaussian tails of this distribution, corresponding to large deviations of $\mathbf{f}$ from $\mathbf{f}^*$, reflect the particular properties of the extinction dynamics of the metapopulation.

The form of the function $S(\mathbf{f})$ is determined by inserting the ansatz (19) into the master equation (14), making use of Eq. (17), and expanding in N^{-1} . One finds a first-order partial differential equation for $S(\mathbf{f})$:

$$0 = H\left(\mathbf{f}, \frac{\partial S(\mathbf{f})}{\partial \mathbf{f}}\right). \quad (20)$$

In our case, for the master equation (14), we obtain:

$$\begin{aligned} H(\mathbf{f}, \mathbf{p}) = & \sum_{j=1}^{\infty} (e^{p_{j+1}-p_j} - 1) b_j f_j + \sum_{j=1}^{\infty} (e^{p_{j-1}-p_j} - 1) d_j f_j \\ & + \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} (e^{p_{i-1}-p_i-p_j+p_{j+1}} - 1) m_i f_i f_j \\ & + \sum_{j=1}^{\infty} (e^{p_{j-1}-p_j+p_1} - 1) m_j f_j \left(1 - \sum_{k=1}^{\infty} f_k\right). \end{aligned} \quad (21)$$

Here $\mathbf{p} = (p_1, p_2, \dots)^\top$, $p_j = \partial S / \partial f_j$ for $j \geq 1$, and $p_0 = 0$.

The solution of Eqs. (20,21) is found by recognising that Eq. (20) is a so-called ‘Hamilton-Jacobi equation’ (Freidlin and Wentzell, 1984). As a consequence, the action $S(\mathbf{f})$ can be determined by solving the set of equations

$$\frac{d\mathbf{f}}{dt} = \frac{\partial H}{\partial \mathbf{p}}, \quad \text{and} \quad \frac{d\mathbf{p}}{dt} = -\frac{\partial H}{\partial \mathbf{f}}. \quad (22)$$

These equations have the form of Hamilton’s equations in classical mechanics with configuration-space variables $\mathbf{f}$. The variables

$$\mathbf{p} = \frac{\partial S}{\partial \mathbf{f}} \quad (23)$$

are therefore referred to as ‘momenta’. An important property of Eq. (22) is that the function $H(\mathbf{f}(t), \mathbf{p}(t))$ remains constant along the ‘trajectories’ $(\mathbf{f}(t), \mathbf{p}(t))$, that is, along the solutions of Eq. (22).

How is the form of $S(\mathbf{f})$ determined by these solutions? The quasi-steady state solution of Eq. (14) corresponds to solutions of Eq. (22) satisfying

$$\left. \begin{array}{l} \mathbf{f}(t) \rightarrow \mathbf{f}^* \\ \mathbf{p}(t) \rightarrow \mathbf{0} \end{array} \right\} \text{as } t \rightarrow -\infty, \quad \mathbf{f}(t) \rightarrow \mathbf{f} \quad \text{as } t \rightarrow \infty, \\ \text{and } H(\mathbf{f}(t), \mathbf{p}(t)) = 0. \quad (24)$$

To every such solution corresponds an action $S(\mathbf{f})$ obtained by integrating the momentum along the path $(\mathbf{f}(t), \mathbf{p}(t))$:

$$S(\mathbf{f}) = \int_{-\infty}^{\infty} dt \mathbf{p}^T \frac{d\mathbf{f}}{dt}. \quad (25)$$

Here $\mathbf{p}^T$ denotes the transpose of the vector $\mathbf{p}$.

The boundary conditions (24) are motivated as follows. Eq. (20) enforces $H = 0$. Further, observe that the stable steady state $\mathbf{f}^*$ of the deterministic dynamics (16) corresponds to a steady state $(\mathbf{f}^*, \mathbf{0})$ of Eq. (22). This can be seen by expanding the function $H(\mathbf{f}, \mathbf{p})$ to second order in $\mathbf{p}$ around $\mathbf{p} = \mathbf{0}$

$$H(\mathbf{f}, \mathbf{p}) = \mathbf{p}^T \mathbf{v}(\mathbf{f}) + \frac{1}{2} \mathbf{p}^T \mathbf{D}(\mathbf{f}) \mathbf{p} + \dots. \quad (26)$$

Here $\mathbf{v}(\mathbf{f})$ is given by Eq. (18), and the symmetric matrix $\mathbf{D}(\mathbf{f})$ has elements $D_{ij} = \partial^2 H / \partial p_i \partial p_j$. The elements are given in appendix A. Eq. (26) shows that the dynamics for $\mathbf{p} = \mathbf{0}$ corresponds to the deterministic dynamics given in Eq. (16). The stability of the steady state $(\mathbf{f}^*, \mathbf{0})$ is determined by the eigenvalues of the matrix

$$\mathbf{J} = \begin{pmatrix} \mathbf{A} & \mathbf{D} \\ \mathbf{0} & -\mathbf{A}^T \end{pmatrix}. \quad (27)$$

The matrix $\mathbf{A}(\mathbf{f})$ has elements $A_{ij} = \partial v_i / \partial f_j$ evaluated at $\mathbf{f} = \mathbf{f}^*$. It is the stability matrix of the stable steady state $\mathbf{f}^*$ of the deterministic dynamics (16). Its elements can be obtained from Eq. (A.2) in appendix A. Similarly, $\mathbf{D}$ is evaluated at $\mathbf{f}^*$. Assuming that the steady state $\mathbf{f}^*$ is stable, the eigenvalues λ_α of $\mathbf{A}$ must have negative real parts. In our case it turns out that the eigenvalues are in fact negative. We write $0 > \lambda_1 > \lambda_2 > \dots$. The eigenvalues of $\mathbf{J}$ occur in pairs λ_α , and $-\lambda_\alpha$. The steady state $(\mathbf{f}^*, \mathbf{0})$ of Eq. (22) is thus a saddle. In other words, stochastic fluctuations allow metapopulations consisting of a finite number of patches to escape from the steady state $\mathbf{f}^*$ (that is stable in the limit $N \rightarrow \infty$) to extinction ($\mathbf{f} = \mathbf{0}$). In general there are (infinitely) many such paths satisfying the boundary conditions (24). Freidlin and Wentzell (1984) formulated a variational principle for the

most likely escape path: in the limit of large values of N , the metapopulation goes extinct predominantly along this path. The quasi-steady state distribution reflects this property: configurations $\mathbf{f}$ along this path are assumed with higher probability. According to the principle described by Freidlin and Wentzell (1984), the most likely escape path is the one with extremal action, Eq. (25).

The picture summarised above is schematically depicted in Fig. 2, for the case where the metapopulation persists in the limit of $N \rightarrow \infty$. Fig. 2a shows the $\mathbf{f}$ - $\mathbf{p}$ plane. As explained above, the point $(\mathbf{f}^*, \mathbf{0})$ corresponds to the stable steady state of the deterministic dynamics, where the infinitely large metapopulation persists. The point $(\mathbf{0}, \mathbf{0})$ corresponds to extinction, it is unstable. Solving Eq. (22) and inserting $\mathbf{p} = \mathbf{0}$ yields the deterministic dynamics (16), connecting these two fixed points. In the limit of $N \rightarrow \infty$, the metapopulation dynamics is constrained to the $\mathbf{f}$ -axis and must approach $\mathbf{f}^*$, as the arrow on the x -axis in Fig. 2a indicates. In other words, in the situation depicted in Fig. 2a extinction never occurs in the limit of $N \rightarrow \infty$.

In finite metapopulations, the situation is entirely different. Fig. 2a illustrates that there is a path from $\mathbf{f}^*$ to $\mathbf{f} = \mathbf{0}$, reaching $\mathbf{f} = \mathbf{0}$ at the so-called ‘fluctuational extinction point’ $(\mathbf{0}, \mathbf{p}^*)$. Along this path, the momenta $\mathbf{p}(t)$ assume non-zero values. These variables characterise the sensitivity of the finite metapopulation to stochastic fluctuations ($\mathbf{p} = \mathbf{0}$ in the deterministic limit $N \rightarrow \infty$ as mentioned above). The form of $S(\mathbf{f})$ (Fig. 2b) is determined by evaluating Eq. (25) along this path, satisfying conditions (24). In the limit of large values of N , the average time to extinction of the metapopulation scales as (Dykman et al., 1994)

$$T_{\text{ext}} = A \exp [NS(\mathbf{f} = \mathbf{0})]. \quad (28)$$

The coefficient A may depend on N , as well as r , K , and m . In the argument of the exponent, only the leading N -dependence is explicit in Eq. (28). The argument of the exponential determines the sensitive dependence of the time to extinction. In one-dimensional problems with a single component f (the case discussed in the review by Ovaskainen and Meerson (2010)), Eq. (25) shows that $S(0)$ is given by the shaded area in Fig. 2a. In the case of our metapopulation model, by contrast, the vector $\mathbf{f}$ has infinitely many components. It is therefore not possible, in general, to find the most likely path from $\mathbf{f}^*$ to the fluctuational extinction point explicitly. In practice one may truncate the dynamics by only considering a finite number of variables f_j (up to a maximal value of j_{max}). This is expected to be a good approximation when j_{max} is taken to be much larger than the carrying capacity K , since $f_j \approx 0$ for $j \gg K$. In our subsequent analysis of the problem

we make use of the fact that the dynamics simplifies considerably in the vicinity of a bifurcation of the deterministic dynamics (Guckenheimer and Holmes, 1983; Dykman et al., 1994).

As mentioned above, near the steady state $\mathbf{f}^*$, the distribution (19) is expected to be Gaussian. This corresponds to an action quadratic in $\delta \mathbf{f} = \mathbf{f} - \mathbf{f}^*$:

$$S(\mathbf{f}) \approx \frac{1}{2} \delta \mathbf{f}^\top \mathbf{C}^{-1} \delta \mathbf{f}. \quad (29)$$

The matrix $\mathbf{C}$, which is the covariance matrix of the distribution (19) multiplied by N , can be obtained from the linearised dynamics, Eq. (22). Using $\mathbf{p} = \partial S / \partial \mathbf{f}$ we have

$$\delta \mathbf{p} = \mathbf{C}^{-1} \delta \mathbf{f}. \quad (30)$$

According to Eq. (24), the dynamics must obey $H(\mathbf{f}(t), \mathbf{p}(t)) = 0$. It follows from Eq. (26) that the linearised dynamics satisfies this constraint provided

$$\mathbf{A}\mathbf{C} + \mathbf{C}\mathbf{A}^\top + \mathbf{D} = \mathbf{0}. \quad (31)$$

This equation determines the covariance matrix $\mathbf{C}$ in Eq. (29) in terms of the matrices $\mathbf{A}$ and $\mathbf{D}$.

3. Results and discussion

In this section we summarise our results for the population dynamics of the metapopulation model described in Section 2.1, using the expansion of the master equation outlined in Section 2.4. This section is divided into two parts. We first discuss the limit of infinitely many patches. Second, we analyse the most likely path to extinction in finite metapopulations. We also summarise our results for the average time to extinction of the metapopulation, and demonstrate that it depends sensitively on upon the parameters of the model (r , K , m , and N).

3.1. Infinitely many patches

It was shown in Section 2.4 that in the limit of infinitely many patches, the metapopulation dynamics is described by the deterministic equation (16), corresponding to the model proposed by Casagrandi and Gatto (1999) and Nachman (2000). In this subsection we briefly summarise our results on the persistence and the relaxation behaviour of the metapopulation model introduced in section 2.1.

3.1.1. Metapopulation persistence in the limit of infinitely many patches ($N \rightarrow \infty$)

For sufficiently large emigration rates m , the deterministic dynamics (16,18) has two viable steady states. The state $\mathbf{f} = \mathbf{0}$ is unstable, and there is a second steady state $\mathbf{f}^*$ given by

$$\begin{aligned} f_j^* &= f_0^* \prod_{k=1}^j \frac{b_{k-1} + I^*}{d_k + m_k} \\ &= f_0^* \left(\frac{rK}{r - \mu} \right)^j \frac{\Gamma(j + I^*/r) \Gamma(1 + z)}{\Gamma(I^*/r) \Gamma(j + 1) \Gamma(j + 1 + z)}, \end{aligned} \quad (32)$$

where $\Gamma(x)$ is the Gamma function, I^* is the rate of immigration into a patch in the steady state, and $z = \mu K / (r - \mu)$. Eq. (32) is most easily understood by recognising that the deterministic dynamics (16,18) takes the form of a master equation for the probabilities f_j that a patch is occupied by j individuals. Eq. (32) is equivalent to Eqs. (5a,b) in (Nachman, 2000) and to Eqs. (5,6) in (Casagrandi and Gatto, 2002). In Eq. (32), the factor f_0^* is a normalisation factor (equal to the frequency of empty patches in the steady state) determined by the requirement that $f_0^* + \sum_{j=1}^{\infty} f_j^* = 1$. Note that the factors in the product in Eq. (32) depend upon the rate I^* . This gives rise to a self-consistency condition for the rate of immigration I^* in the steady state:

$$I^* = \sum_{j=1}^{\infty} m_j f_j^*. \quad (33)$$

The steady state (32) is stable provided the eigenvalues of $\mathbf{A}$ (this matrix is introduced in the previous section and its elements are given in appendix A) have negative real parts. This is the case when the steady-state immigration rate I^* is larger than zero. The steady-state immigration rate is expected to decrease when the emigration rate decreases. Consider for instance decreasing m , defined in Eq. (4), while keeping all other parameters constant. As m approaches a critical value, m_c , we observe that $I^* \rightarrow 0$. At the same time all components of $\mathbf{f}^*$ tend to zero, and $f_0^* \rightarrow 1$. Below this critical point, that is for $m < m_c$, the stable steady state ceases to exist (and $\mathbf{f} = \mathbf{0}$ turns stable). In the limit of infinitely many patches ($N \rightarrow \infty$), the persistence condition

$$m > m_c \quad (34)$$

ensures that a stable steady state exists, with $f_j^* > 0$ for some non-zero values of j . This persistence criterion for infinitely large metapopulations is equivalent to the

criterion suggested by Chesson (1984) and re-derived by Casagrandi and Gatto (2002), namely that the metapopulation persists provided that the expected number of emigrants from a patch with initially one individual and into which immigration is excluded is greater than unity. In a slightly different form this principle is quoted by Hanski (1998), namely that the expected number of successful colonisations out of a given patch during its lifetime in an otherwise empty metapopulation should be larger than unity. We emphasise that this criterion (or any of the equivalent criteria, such as (34)) cannot be used to determine how stochastic fluctuations in finite metapopulations affect their persistence.

The critical value m_c is obtained by analysing the steady-state condition (33) for m close to m_c . We write

$$m = m_c(1 + \delta) \quad (35)$$

and expand the steady-state immigration rate in powers of δ (note that I^* vanishes at $\delta = 0$):

$$I^* = I_1\delta + I_2\delta^2 + \dots \quad (36)$$

The constant I_1 is given in appendix B. Expanding Eq. (33), we find to lowest order in δ a condition for m_c :

$$d_1 = m_c \sum_{j=2}^{\infty} j \prod_{k=2}^j \frac{b_{k-1}}{d_k + m_c k}. \quad (37)$$

Fig. 3 shows how the solution m_c of Eq. (37) depends upon the carrying capacity K for the model introduced in section 2.1. The critical migration rate is shown as a solid line in the left panel of Fig. 3, in the following referred to as the ‘critical line’. Above this line, a metapopulation consisting of an infinite number of patches persists. Expanding the condition (37) for large carrying capacities K we find that (see appendix C):

$$m_c \sim r \sqrt{\frac{r-1}{2\pi K}} \exp\left[-K\left(1 - \frac{\log r}{r-1}\right)\right]. \quad (38)$$

Fig. 3 also shows f_j^* as a function of j for six stable steady states corresponding to different values of m and K . Results similar to those shown in the six panels on the right-hand side of Fig. 3 are given in Fig. 2 in (Nachman, 2000), and in Fig. 2 **a-c** in (Casagrandi and Gatto, 2002).

One observes how the number of empty patches f_0^* tends towards unity as the critical line is approached. To leading order in δ we have:

$$f_0^* = 1 - c_1\delta. \quad (39)$$

The constant c_1 is given in appendix B. Similarly, the expected number of individuals per patch approaches zero:

$$\sum_{j=1}^{\infty} j f_j^* \sim c_2 \delta \quad (40)$$

as $\delta \rightarrow 0$. The constant c_2 is given in appendix B. Fig. 4 shows the average number of individuals per patch, and $1 - f_0^*$ as a function of m . Shown are numerical solutions of the steady-state condition (33), solid lines, of Eqs. (39) and (40), dashed lines, and of direct numerical simulations, symbols, of the metapopulation model described in section 2.2. The numerical experiments were performed for $N = 50, 100$ and 1000 patches and averaged over an ensemble of different realisations. In principle, in a finite metapopulation no stable steady states exist with $f_j^* > 0$ for some $j \geq 1$. But the larger the number of patches, the larger the average time to extinction is expected to be. $N = 1000$, it turns out, is sufficiently large for the parameter values chosen that extinction did not occur during the simulations. Consequently we observe good agreement between the direct numerical simulations and the numerical solution of the deterministic steady-state condition. When the number of patches is small, by contrast, this is no longer the case. In order to determine the quasi-steady state in such cases, the simulations must be run for a time large enough for the initial transient to die out, but shorter than the expected time to extinction. Stochastic realisations leading to extinction during the simulation time must be discarded.

3.1.2. Relaxation dynamics in the limit of $N \rightarrow \infty$ and Levins' model

We continue to discuss metapopulations with infinitely many patches. In this section we analyse how the metapopulation relaxes to the stable steady state $\mathbf{f}^*$. This question is important for two reasons. First, when the relaxation time is much smaller than the expected time to extinction (that is, when the number of patches is large enough), Eq. (16) describes the relaxation dynamics well. Second, and more importantly, the deterministic dynamics exhibits a ‘slow mode’ in the vicinity of the critical line (in Fig. 3): for small values of δ , it turns out, there is a particular linear combination of the variables f_j that relaxes slowly, with a rate proportional to δ . This slow mode dominates the relaxation dynamics which is thus essentially one-dimensional for small values of δ . This fact is well known in the theory of dynamical systems (Guckenheimer and Holmes, 1983), see also Dykman et al. (1994). For our model, this fact has important implications. Essentially, the deterministic dynamics close to the critical line in Fig. 3 reduces to Levins' model, as we demonstrate in this section.

Fig. 5 shows the relaxation of the average number of individuals and of the frequency of empty patches f_0 to their values in the stable steady state $\mathbf{f}^*$, for three different initial conditions. Shown are numerical solutions of Eqs. (16,18), solid lines, as well as results of direct numerical simulations, symbols. The numerical experiments were performed for $N = 50, 100$ and 1000 patches, and averaged over 100 realisations. Even for 50 patches, and for the parameter values chosen in Fig. 5, the average time to extinction is large enough so that extinction did not occur in the numerical simulations. The agreement between the direct numerical simulations for $N = 1000$ and the solution of Eqs. (16,18) is good. For $N = 50$ and 100 we can observe deviations to the solution of Eqs. (16,18). Here the effect of the finite number N of patches becomes apparent.

In general Eqs. (16,18) must be solved numerically. We now show that the deterministic dynamics simplifies considerably close to the critical line in Fig. 3, when δ is small. At $\delta = 0$ we have that $I^* = 0$, $f_0^* = 1$ and consequently $\mathbf{f}^* = \mathbf{0}$. For small positive values of δ , the components of $\mathbf{f}^*$ are of order δ , and we expand Eq. (16) in powers of δ and $\mathbf{f}$ (Dykman et al., 1994):

$$v_i = \sum_j A_{ij}^{(0)} f_j + m_c \delta \sum_j A_{ij}^{(1)} f_j + \frac{1}{2} m_c (1 + \delta) \sum_{jk} A_{ijk}^{(2)} f_j f_k. \quad (41)$$

Here $A_{ij}^{(0)}$ are the elements of the matrix $\mathbf{A}$ evaluated at the critical line ($\delta = 0$). They are obtained from (A.2):

$$\begin{aligned} A_{ij}^{(0)} &= b_{i-1} \delta_{i-1j} + (d_{i+1} + m_c(i+1)) \delta_{i+1j} \\ &\quad - (b_i + d_i + m_c i) \delta_{ij} \quad \text{for } i > 1, \\ A_{1j}^{(0)} &= (d_2 + 2m_c) \delta_{j2} - (b_1 + d_1 + m_c) \delta_{j1} + m_c j. \end{aligned} \quad (42)$$

The slow mode exists because this matrix has one zero eigenvalue, $\lambda_1^{(0)}$. All other eigenvalues are negative. At finite but small values of δ the corresponding matrix (A.2) evaluated at the steady state $\mathbf{f}^*$ has one small eigenvalue, $\lambda_1 \sim -\delta$. To identify the slow mode we diagonalise $\mathbf{A}^{(0)}$ given by (42). Since this matrix is not symmetric, its left and right eigenvectors differ:

$$\mathbf{A}^{(0)} \mathbf{R}_\alpha = \lambda_\alpha^{(0)} \mathbf{R}_\alpha, \quad \mathbf{L}_\beta^\top \mathbf{A}^{(0)} = \mathbf{L}_\beta^\top \lambda_\beta^{(0)}, \quad \text{for } \alpha, \beta = 1, 2, \dots \quad (43)$$

Here $\mathbf{L}_\alpha^\top = (L_{1\alpha}, L_{2\alpha}, \dots)$ denotes a left eigenvector with components $L_{1\alpha}, L_{2\alpha}, \dots$. $\mathbf{R}_\alpha$ denotes a right eigenvector with components $R_{1\alpha}, R_{2\alpha}, \dots$. We take the eigenvectors to be bi-orthonormal, $\mathbf{L}_\beta^\top \mathbf{R}_\alpha = \delta_{\alpha\beta}$. As before, the eigenvalues are ordered

as $0 \geq \lambda_1^{(0)} > \lambda_2^{(0)} > \dots$. Multiplying Eq. (41) from the left with $\mathbf{L}_\alpha^\top$ and making use of Eq. (16) yields the equations of motion of $Q_\alpha = \mathbf{L}_\alpha^\top \mathbf{f}$ (that is, the equations governing the time-evolution of Q_α):

$$\begin{aligned} \frac{dQ_\alpha}{dt} = & \mathbf{L}_\alpha^\top \mathbf{A}^{(0)} \mathbf{f} + m_c \delta \sum_{ij\beta} L_{\alpha i} A_{ij}^{(1)} R_{\beta j} Q_\beta \\ & + \frac{1}{2} m_c (1 + \delta) \sum_{ijk\mu\nu} L_{\alpha i} A_{ijk}^{(2)} R_{\mu j} R_{\nu k} Q_\mu Q_\nu. \end{aligned} \quad (44)$$

At $m = m_c$ (that is, for $\delta = 0$) we have that $\lambda_1 = \lambda_1^{(0)} = 0$. For small values of δ we find $|\lambda_1| \ll |\lambda_\alpha|$ for $\alpha > 1$. While λ_α , $\alpha > 1$, approach constants as $\delta \rightarrow 0$, $\lambda_1 = \mathbf{L}_1^\top \mathbf{A} \mathbf{R}_1 \propto -\delta$ tends to zero in this limit. This implies

$$\left| \frac{dQ_1}{dt} \right| \ll \left| \frac{dQ_\alpha}{dt} \right| \quad \text{for } \alpha > 1. \quad (45)$$

In the following, Q_1 is therefore referred to as ‘slow mode’, whereas Q_α for $\alpha > 1$ are termed fast variables. As explained by Dykman et al. (1994), the fast variables rapidly approach quasi-steady states

$$Q_\alpha \approx -\frac{a_{\alpha 1} \delta Q_1 + a_{\alpha 2} Q_1^2}{\lambda_\alpha^{(0)}} \quad \text{for } \alpha > 1 \quad (46)$$

that depend on the instantaneous value of the slow variable, Q_1 . Terms including fast variables (Q_α for $\alpha > 1$) are not kept on the right-hand side of Eq. (46) because they are of higher order in δ . This is a consequence of the fact that close to the steady state, Q_1 is of order δ . Eq. (46) is correct to order δ^2 . The coefficients $a_{\alpha 1}$ and $a_{\alpha 2}$ are given by

$$\begin{aligned} a_{\alpha 1} &= m_c \sum_{ij} L_{\alpha i} A_{ij}^{(1)} R_{1j}, \\ a_{\alpha 2} &= \frac{m_c}{2} \sum_{ijk} L_{\alpha i} A_{ijk}^{(2)} R_{1j} R_{1k}, \end{aligned} \quad (47)$$

for $\alpha = 1, 2, \dots$. The elements $A_{ij}^{(1)}$ and $A_{ijk}^{(2)}$ are given in appendix A. The equation of motion for the slow mode Q_1 is to third order in δ :

$$\begin{aligned} \frac{dQ_1}{dt} = & a_{11} \delta Q_1 + a_{12} (1 + \delta) Q_1^2 \\ & + \text{terms of order } \delta^3 \text{ involving } Q_\beta \text{ for } \beta > 1 \\ & + \text{terms of higher order in } \delta. \end{aligned} \quad (48)$$

In the remainder of this subsection we neglect the δ^3 -terms and higher-order terms in Eq. (48). The δ^3 -terms are discussed in subsection 3.2. To second order in δ , the equation of motion for Q_1 is:

$$\frac{dQ_1}{dt} = a_{11}\delta Q_1 + a_{12}Q_1^2. \quad (49)$$

According to Eq. (47), the coefficients a_{11} and a_{12} are given in terms of the components L_{1j} of the left eigenvector $\mathbf{L}_1$ and the components R_{1j} of the right eigenvector $\mathbf{R}_1$ of $\mathbf{A}^{(0)}$. For the right eigenvector we find, from Eqs. (42) and (43),

$$R_{1j} = R_{11} \prod_{k=2}^j \frac{b_{k-1}}{d_k + m_c k} \quad \text{for } j > 1, \quad (50)$$

the first component being R_{11} . For the left eigenvector, we obtain the following recursion (with the boundary condition $L_{1j} = 0$ for $j = -1$):

$$L_{1j+1} - L_{1j} = \frac{d_j + m_c j}{b_j} (L_{1j} - L_{1j-1}) - \frac{m_c j}{b_j} L_{11}. \quad (51)$$

This recursion is solved by:

$$\begin{aligned} L_{11}, \quad L_{12} &= L_{11} \left(1 + \frac{d_1}{b_1} \right), \quad \text{and} \\ L_{1j} &= L_{11} \left(1 + \frac{d_1}{b_1} + \frac{m_c}{b_1} \sum_{n=2}^{j-1} \sum_{k=n+1}^{\infty} \frac{k R_{1k}}{n R_{1n}} \right) \quad \text{for } j > 2. \end{aligned} \quad (52)$$

We show in appendix C that the elements of $\mathbf{L}_1^\top$ approach the following limiting form as $K \rightarrow \infty$:

$$L_{11}, \quad L_{12} = L_{11} \frac{r+1}{r}, \quad \text{and} \quad L_{1j} = L_{11} r \frac{1-r^{-j}}{r-1}. \quad (53)$$

We choose L_{11} such that L_{1j} approaches unity for $j \gg 1$ as $K \rightarrow \infty$. This corresponds to the choice $L_{11} = (r-1)/r$, resulting in

$$L_{1j} = 1 - r^{-j} \quad (54)$$

in the limit of $K \rightarrow \infty$. In this limit, and for large values of r , we see that $\mathbf{L}_1^\top$ approaches the vector $(1, 1, \dots)$. The convention leading to Eq. (54) also fixes R_{11}

which must be chosen so that $\mathbf{L}_1^\top \mathbf{R}_1 = 1$. Explicit expressions for a_{11} and a_{12} , obtained from Eqs. (47), (50), and (52) are given in appendix B.

Eq. (49) has two steady states $Q_1 = 0$ and $Q_1^* = -a_{11}\delta/a_{12}$. Note that Q_1^* is positive since $a_{12} < 0$. These two steady states correspond to the steady states $\mathbf{f} = 0$ and $\mathbf{f}^*$ of Eq. (16). Comparison with Eq. (32) shows that $\mathbf{R}_1$ is proportional to $\mathbf{f}^*$ to lowest order in I^* (that is, to lowest order in δ). In fact we have

$$\mathbf{f}^* = \mathbf{R}_1 Q_1^* + \text{higher orders in } \delta. \quad (55)$$

Fig. 6 illustrates how the deterministic dynamics relaxes to the stable steady state $\mathbf{f}^*$. Shown are the expected number of individuals per patch, $\sum_j j f_j$ and the fraction of empty patches as functions of time, determined from numerical solutions of Eqs. (16,18). Curves for three different initial conditions are shown (solid lines). The corresponding solutions of Eq. (49) are shown as dashed lines. Initially the variable Q_1 is not much slower than the Q_α -variables for $\alpha > 1$, and the approximate one-dimensional dynamics (49) is not a good approximation. But the solution of Eqs. (16,18) rapidly relaxes to a form where Q_1 becomes a slow mode, and Eq. (49) accurately describes the slow approach to the steady state.

Comparing Eqs. (49) and (1) shows that the slow mode Q_1 obeys Levins' equation. The results of this subsection allow us to compute e and c in terms of r , K , and δ . We find to order δ

$$\begin{aligned} c - e &= a_{11}\delta, \\ c &= -a_{12} + \text{terms of order } \delta. \end{aligned} \quad (56)$$

The contributions to c of order δ can be computed explicitly using the formulae derived above. For the sake of brevity we do not specify these contributions here. In Sec. 3.2.3 we give an explicit formula valid in the limit of large K .

We see that that Levins' model describes the dynamics of the metapopulation regardless of whether the patches are strongly coupled or not, provided the metapopulation is sufficiently close to criticality (that is, close to the critical line in Fig. 3). But we emphasise that in general the slow variable is not the fraction of occupied patches as envisaged by Levins. The variable Q_1 is given by $\mathbf{L}_1^\top \mathbf{f}$. Fig. 7 shows how the components L_{1j} of $\mathbf{L}_1$ depend upon j . When the local population dynamics is fast compared to the migration dynamics (for $r = 1.5$ and $K = 50$), the vector is approximately given by $(1, 1, 1, \dots)$, see also Eq. (54). In this case, Q_1 is approximately equal to the fraction Q of occupied patches. This is the limit of time-scale separation considered by Levins. We have thus derived the coefficients appearing in Eq. (1) from a stochastic, individual-based metapopulation

model defined in terms of the life history of its inhabitants (given by local birth and death rates, as well as the emigration rate). The asymptotic behaviours of a_{11} and a_{12} for large values of K are given by (see appendix C):

$$a_{11} \sim -a_{12} \sim \sqrt{\frac{K(r-1)^3}{2\pi}} \exp\left[-K\left(1 - \frac{\log r}{r-1}\right)\right]. \quad (57)$$

When the patches are strongly mixed by migration, then the interpretation of Q_1 is different. Fig. 7 shows that for $r = 1.05$ and $K = 10$, the components L_{1j} are roughly proportional to j in the relevant range of j (where f_j^* is not too small). In this case, therefore, the slow mode is interpreted as the average number of individuals per patch, which in turn is proportional to the immigration rate, Eq. (11).

In summary, in this section we have shown how the deterministic metapopulation dynamics simplifies in the vicinity of the bifurcation (critical line in Fig. 3), that is, for small values of δ . In this limit, the deterministic dynamics is essentially one-dimensional, and of the same form as the deterministic equation for the fraction of occupied patches originally suggested by Levins (1969). Commonly it is argued that the form of Eq. (1) is appropriate when the local dynamics is much faster than migration. We have seen that this is not a necessary condition. In general, Eq. (1) describes the deterministic dynamics of metapopulations on the brink of extinction (for small values of δ). We find that the variable Q is indeed given by the fraction of occupied patches when the local-patch dynamics is fast. In general, however, Q has a different interpretation. Finally, we have been able to relate the rates c and e to the parameters of the individual-based, stochastic model (namely r , K , and $\delta = (m - m_c)/m_c$).

Last but not least we emphasise that patch extinction in our model is entirely due to demographic fluctuations. It is possible to generalise our model so that the extinction rate accounts, in addition, for environmental stochasticity, possibly including ‘killing’ (Coolen-Schrijner and van Doorn, 2006): transitions from an arbitrary state of a patch directly to extinction of that patch, local catastrophes in other words.

3.2. Finite number of patches

In the previous section we summarised our results on metapopulation dynamics in the limit of $N \rightarrow \infty$. The subject of the present section is the dynamics for metapopulations consisting of a finite number N of patches. In this case the fluctuations inherent in the birth-, death- and migration processes lead to fluctuations around the steady state $\mathbf{f}^*$. When the number of patches is large, these fluctuations are expected to be small. But they are essential: in a finite metapopulation

the only absorbing state is $\mathbf{f} = \mathbf{0}$. In other words, the fluctuations turn the stable steady state $\mathbf{f}^*$ of the deterministic dynamics into an unstable one.

3.2.1. Fluctuations around the quasi-steady state

For finite values of N , the population fluctuates around its quasi-steady state, as pointed out in section 2.4.2. These fluctuations are Gaussian and of order N^{-1} (cf. Eqs. (19) and (29)). Fig. 8a shows how the standard deviation of the fraction of empty patches, σ_0 , depends on the number of patches, N . The standard deviation is calculated from the covariance matrix $\mathbf{C}$, Eq. (31), as

$$\sigma_0^2 = \langle f_0^2 \rangle - \langle f_0 \rangle^2 = \frac{1}{N} \sum_{i,j=1}^{\infty} C_{ij}. \quad (58)$$

Comparing the analytical approximation of σ_0 , calculated using Eqs. (31,58), with simulations of the full stochastic model, we find good agreement when $N \geq 100$. Fig. 8b shows the variance for each $\sigma_j^2 = \langle f_j^2 \rangle - \langle f_j \rangle^2$ as a function of j , for $N = 100$.

3.2.2. Most likely path to extinction at finite but large values of N

When the number of patches is large, the state $\mathbf{f}^*$ may be very long-lived (and is thus referred to as a quasi-steady state). The methods described in section 2.4 allow us to systematically analyse the properties of this quasi-steady state in terms of Eq. (22). While the deterministic dynamics in the limit of $N \rightarrow \infty$ is given by Eq. (16), Eq. (22) describes the stochastic fluctuations of the quasi-stable distribution at finite values of N prior to extinction. We note that by setting $\mathbf{p} = \mathbf{0}$ in the equations of motion [Eq. (22)], the deterministic dynamics [Eq. (16)] is obtained. In order to describe the fluctuations of a finite metapopulation around $\mathbf{f}^*$ we need to find the most likely path from $\mathbf{f}^*$ to a point $\mathbf{f}$ in the vicinity, namely the path from $\mathbf{f}^*$ to $\mathbf{f}$ with extremal action [Eq. (25)], satisfying $H(\mathbf{f}(t), \mathbf{p}(t)) = 0$, as well as the boundary condition [Eq. (30)].

The tails of the quasi-steady state distribution near $\mathbf{f} = \mathbf{0}$ are obtained by computing the path from $\mathbf{f}^*$ to $\mathbf{f} = \mathbf{0}$ with extremal action. This path is termed the most likely path to extinction, because in the limit of large values of N the trajectories of the stochastic, individual-based dynamics to extinction are expected to fluctuate tightly around this path. The most likely path to extinction leaves the saddle point $(\mathbf{f}^*, \mathbf{0})$ along an unstable direction. Therefore this path cannot directly connect to the origin $(\mathbf{0}, \mathbf{0})$. It turns out that the dynamics (22) exhibits a saddle

point at $\mathbf{f} = \mathbf{0}$ and at non-vanishing momenta, which we call $\mathbf{p}^*$. The steady-state condition $d\mathbf{p}/dt = \mathbf{0}$ gives rise to a recursion relation for the momentum components of $\mathbf{p}^*$ of this saddle point:

$$e^{p_{k+1}^* - p_k^*} - 1 = \frac{d_k}{b_k}(1 - e^{-p_k^* + p_{k-1}^*}) + \frac{m_k}{b_k}(1 - e^{p_1^* - p_k^* + p_{k-1}^*}). \quad (59)$$

The problem lies in finding the most likely path from $(\mathbf{f}^*, \mathbf{0})$ to $(\mathbf{0}, \mathbf{p}^*)$. The manifold connecting these two points is infinite dimensional. It is straightforward to truncate the system of equations (22) at some large value of j , but finding the extremal path in the high-dimensional manifold (for instance by a numerical shooting method starting in the vicinity of $\mathbf{f}^*$) is very difficult.

However, the problem simplifies considerably in vicinity of the critical line in the left panel of Fig. 3. When δ is small, the dynamics (22) is approximately two-dimensional (Dykman et al., 1994), since the linearisation (27) has two small eigenvalues when $\delta \ll 1$. At $\delta = 0$ we write

$$\begin{aligned} \mathbf{J}^{(0)} \mathcal{R}_\alpha &= \lambda_\alpha^{(0)} \mathcal{R}_\alpha, \\ \mathbf{J}^{(0)} \mathcal{R}'_\alpha &= -\lambda_\alpha^{(0)} \mathcal{R}'_\alpha, \end{aligned} \quad (60)$$

and corresponding equations for the left eigenvectors $\mathcal{L}_\alpha^\top$ and $\mathcal{L}'_\alpha{}^\top$. Here $\mathbf{J}^{(0)}$ denotes the matrix $\mathbf{J}$ (see Eq. (27)) evaluated at $\delta = 0$, and $\lambda_\alpha^{(0)}$ are the eigenvalues of $\mathbf{A}^{(0)}$. The left and right eigenvectors of $\mathbf{J}^{(0)}$ can be written in terms of those of $\mathbf{A}^{(0)}$:

$$\mathcal{R}'_\alpha = \begin{pmatrix} \mathbf{0} \\ \mathbf{L}_\alpha \end{pmatrix}, \quad \text{and} \quad \mathcal{R}_\alpha = \begin{pmatrix} \mathbf{R}_\alpha \\ \mathbf{0} \end{pmatrix}. \quad (61)$$

The left eigenvectors are given by

$$\mathcal{L}'_\alpha{}^\top = (\mathbf{0}, \mathbf{R}_\alpha^\top), \quad \text{and} \quad \mathcal{L}_\alpha{}^\top = (\mathbf{L}_\alpha^\top, \mathbf{0}). \quad (62)$$

The slow variables are obtained by projecting $(\mathbf{f}, \mathbf{p})^\top$ onto $\mathcal{L}_1^\top$ and $\mathcal{L}'_1{}^\top$. They are thus simply given by Q_1 and P_1 , where

$$Q_\alpha = \mathbf{L}_\alpha^\top \mathbf{f} \quad \text{and} \quad P_\alpha = \mathbf{p}^\top \mathbf{R}_\alpha. \quad (63)$$

Following Dykman et al. (1994), the slow dynamics of Q_1 and P_1 is found by expanding the Hamiltonian (21) in powers of δ , $\mathbf{f}$, and $\mathbf{p}$. Starting from Eq. (26), we use Eq. (41), as well as an expansion of $\mathbf{D}(\mathbf{f})$ in powers of $\mathbf{f}$: noting that $\mathbf{D}$ vanishes at criticality, we write

$$D_{ij} = \sum_{k=1}^{\infty} B_{ijk}^{(1)} f_k + \dots \quad (64)$$

The elements of $B_{ijk}^{(1)} = \partial D_{ij} / \partial f_k$ are given in appendix A. $H(Q_1, P_1)$ has the form (to third order in δ)

$$H(Q_1, P_1) = P_1(a_{11}\delta Q_1 + a_{12}Q_1^2) + b_{11}Q_1P_1^2. \quad (65)$$

The coefficients

$$b_{11} = \frac{1}{2} \sum_{ijk} L_{1i} B_{ijk}^{(1)} L_{1j} R_{1k}, \quad (66)$$

and a_{11} , a_{12} are given in appendix B. The equation of motion for Q_1 and P_1 is

$$\frac{dQ_1}{dt} = \frac{\partial H}{\partial P_1} \quad \text{and} \quad \frac{dP_1}{dt} = -\frac{\partial H}{\partial Q_1}. \quad (67)$$

The dynamics determined by Eqs. (65,67) is illustrated in Fig. 9, similar to Fig. 2. The three steady states of Eqs. (65,67) of interest for the questions addressed here are:

$$Q_1 = 0 \quad \text{and} \quad P_1 = 0, \quad (68)$$

$$Q_1 = 0 \quad \text{and} \quad P = P_1^* = -a_{11}\delta/b_{11}, \quad (69)$$

$$Q_1 = Q_1^* = -a_{11}\delta/a_{12} \quad \text{and} \quad P_1 = 0. \quad (70)$$

All three steady states are saddle points. The steady state (70) corresponds to the saddle point $(\mathbf{f}^*, \mathbf{0})$ of the dynamics (22). Note that $a_{12} < 0$. The steady state (69) corresponds to the saddle point $(\mathbf{0}, \mathbf{p}^*)$ which lies at the end of the most likely path to extinction. In one-dimensional single-step birth-death processes, the corresponding point is commonly referred to as ‘fluctuational extinction point’. To lowest order in δ we find for the solution $\mathbf{p}^*$ of Eq. (59)

$$\mathbf{p}^* = P_1^* \mathbf{L}_1 + \text{higher orders in } \delta. \quad (71)$$

Eq. (71) furnishes an interpretation of the left eigenvector $\mathbf{L}_1^\top$ for small values of δ . This vector is proportional to the vector $\mathbf{p}^*$, and the components of this vector define the coordinates of the fluctuational extinction point. In one-dimensional birth-death processes, the corresponding value is given by $p^* = -\log R_0$ where R_0 is the reproductive value. An example is the so-called SIS-model (Doering et al., 2005; Assaf and Meerson, 2010), a stochastic model for the duration of the epidemic state of an infectious disease. Here the reproductive value R_0 is the expected number of infections caused, during its lifetime, by one infected individual introduced into a susceptible population. In infinite populations the epidemic persists

provided $R_0 > 1$. This criterion is precisely analogous to the persistence criteria discussed in Sec. 2.4.2. When R_0 is only slightly larger than unity, $R_0 = 1 + \epsilon$, say, then $p^* \approx -\epsilon$.

In our case, the vector $\mathbf{L}_1^\top$ plays the role of a reproductive *vector* (Fisher, 1930; Samuelson, 1977). Expanding the solution of the linearised deterministic dynamics (16), in terms of the eigenvectors of $\mathbf{A}^{(0)}$ yields

$$\begin{aligned} \delta \mathbf{f}(t) &= \sum_{\alpha=1}^{\infty} e^{\lambda_{\alpha} t} \mathbf{R}_{\alpha} \mathbf{L}_{\alpha}^{\top} \delta \mathbf{f}(0) \\ &\sim e^{\lambda_1 t} \mathbf{R}_1 \mathbf{L}_1^{\top} \delta \mathbf{f}(0) \quad \text{at large times.} \end{aligned} \quad (72)$$

We see that the components L_{1j} of the vector $\mathbf{L}_1$ determine how much fluctuations of the number of patches with j individuals contribute to the relaxation towards the steady state in infinite metapopulations. In other words, the components of $\mathbf{L}_1$ determine the susceptibility of patches with j individuals to stochastic fluctuations. We shall see below that this susceptibility determines the average time to extinction. We note that the correspondence (71) implies that the solution of the recursion (59) for p_j^* must be equivalent, to lowest order in δ , to the recursion (51) for the components of $\mathbf{L}_1$, up to a factor. This is indeed the case. In analogy with the SIS-model discussed above, the coordinates of the vector $\mathbf{L}_1^\top$ parameterise the fluctuational extinction point.

Finally we note that the components of $\mathbf{L}_1$ have a simple interpretation in the limit of $K \rightarrow \infty$. Comparing Eqs. (54) and (C.19) we see that the component L_{1j} is given by the probability of a single, isolated patch with j individuals to eventually reach its carrying capacity, K . This observation concludes our discussion of the nature of the fluctuational extinction point of Eq. (67).

The most likely escape path leads from the saddle (70) to the fluctuation extinction point (69). The path is parameterised by Q_1 and P_1 . Solving $H = 0$ for P_1 we find from Eq. (65) (discarding the trivial solution $Q_1 = P_1 = 0$)

$$P_1 = -b_{11}^{-1}(a_{11}\delta + a_{12}Q_1). \quad (73)$$

This path corresponds to the straight line from $(Q_1^*, 0)$ to $(0, P_1^*)$ in Fig. 9. Eq. (73) together with Eqs. (55) and (71) imply that the $\mathbf{f}$ - and $\mathbf{p}$ -spectra move rigidly towards extinction. In other words, our analysis shows that on the path to extinction, both $\mathbf{f}(t)$ and $\mathbf{p}(t)$ retain their shape (initially given by the right and left eigenvectors $\mathbf{R}_1$ and $\mathbf{L}_1^\top$ of $\mathbf{A}^{(0)}$) to lowest order in δ .

In the limit of large carrying capacities (where the critical emigration rate is small) one might expect that patches become extinct independently of each other.

In this limit, the rate of extinction of single patches in the population is small, and the $\mathbf{f}$ -spectrum relaxes rapidly to its rigid shape once a given patch has gone extinct. It is important to emphasise that the patches are nevertheless coupled by migration which gives rise, in this limit, to a small rate of colonisation of empty patches. Thus the average time T_{ext} to extinction for the whole system is not determined by the largest time of extinction of the N single patches (we discuss the time T_{ext} in the following subsection). This has strong implications for conservation biology: it indicates the importance of protecting available (possibly empty) patches, even if they are small and prone to extinction.

When the population is strongly mixed by migration, on the other hand, it is surprising that the $\mathbf{f}$ - and $\mathbf{p}$ -spectra move rigidly to extinction. Migration upholds a balance that causes the shape of the $\mathbf{f}$ -spectrum to remain unchanged as the metapopulation comes closer to extinction. In other words, just the normalisation $1 - f_0$ changes.

We have attempted to verify the predictions of this subsection by direct numerical simulations of the stochastic, individual-based model. The result is shown in Fig. 10. The simulations were performed as follows. For 10,000 independent realisations we followed the metapopulation to extinction. For each realisation we analysed the path to extinction by tracing the stochastic trajectory back in time, starting at the time of extinction. We traced the trajectories back for the average time it takes to reach, using this procedure, the number of individuals that corresponds to the quasi-steady state. As a function of time, the average number of individuals per patch and the fraction of occupied patches was computed. Fig. 10 shows the probability of observing a given number of individuals in occupied patches, conditional on the fraction of occupied patches, $1 - f_0$. The probability is colour coded: white corresponds to high probability, black to low probability. The left panel of Fig. 10 is consistent with the prediction that the $\mathbf{f}$ -spectrum moves rigidly. This is not the case for the case shown in the right panel of Fig. 10. Here δ is too large, the two-dimensional approximation to the full Eq. (22) is not accurate.

An alternative representation of the most likely path to extinction is depicted in Fig. 11. Employing the same simulations described above, Fig. 11 shows the average number n_j of patches with j individuals conditional on the total number of individuals, compared with results obtained by numerically integrating Eq. (22). We observe that the agreement is good up to a point where n_j becomes too small. When the total number of individuals is small (less than approximately 30 for the parameters in Fig. 11) discrete effects start to dominate, and the large- N expansion of the master equation fails to accurately describe the last part of the trajectory

towards extinction.

3.2.3. Time to extinction for finite but large values of N

The tail of the quasi-steady state distribution (19) towards $\mathbf{f} = \mathbf{0}$ determines the average time to extinction, Eq. (28):

$$T_{\text{ext}} = A \exp(NS). \quad (74)$$

The coefficient A may depend on N , as well as on r , K , and m . We have not been able to determine it. The action $S \equiv S(\mathbf{f} = \mathbf{0})$ is a function of r , K , and m . Since NS appears in the argument of the exponential in Eq. (74), the average time to extinction depends sensitively upon the number N of patches, and on S . Close to the critical line in Fig. 3 we find the action by integrating P_1 along the path given by Eq. (73). This yields:

$$S = -\frac{\delta^2}{2} \frac{a_{11}^2}{b_{11}a_{12}} \quad (75)$$

which corresponds to the shaded area in Fig. 9. Note that $a_{12} < 0$. The prediction for S , Eq. (75), is compared to results of direct simulations in Fig. 12. The initial condition for the direct simulations was chosen as follows. First $\mathbf{f}^*$ was calculated, this determines the initial state $\mathbf{n} = N\mathbf{f}^*$. Note however that the components n_j of $\mathbf{n}$ must be integers. For small values of δ , all $n_{j>0}$ may round to zero, inconsistent with the constraint $\sum_j n_j = N$. In such cases we grouped counts n_j corresponding to neighbouring values of j together before rounding. The action S was determined by plotting $\log T_{\text{ext}}$ as a function of N . For sufficiently large values of N (such that $NS \gg 1$) one expects a straight line. We perform a linear regression by least squares to determine the slope S/δ^2 . Fig. 12 shows $\log T_{\text{ext}}$ as a function of $N\delta^2$. The approximations leading to Eq. (75) require that N is large and δ small. Eq. (74) is expected to be a good approximation provided

$$(NS)^{-1/2} \ll \delta \ll 1. \quad (76)$$

The data shown in Fig. 12 are consistent with this expectation. We see that the fitted values of S approach the analytical result, Eq. (75) as δ is decreased (right panels in Fig. 12). This figure illustrates the sensitive dependence of the time to extinction upon r , K , δ , and N .

In Fig. 13 we summarise our best estimates for S/δ^2 for different values of r and K (and for the smallest value of δ for which we obtained reliable results). These estimates are compared to the analytical result, Eq. (75). We observe good agreement. Fig. 13 appears to indicate that S/δ^2 approaches the value $1/2$ as K

increases. The approach appears to be the faster the larger the value of r is. In order to demonstrate that this is in fact true, we have determined the asymptotic dependency of the coefficient b_{11} upon K in the limit of large values of K . We find (see appendix C):

$$b_{11} \sim \sqrt{\frac{K(r-1)^3}{2\pi}} \exp\left[-K\left(1 - \frac{\log r}{r-1}\right)\right]. \quad (77)$$

This result, taken together with Eq. (57) determines the limiting value of S/δ^2 to be $1/2$. Fig. 13 shows that already for $r = 1.5$ and $K = 25$ the value of S/δ^2 is very close to this limiting value. We note that while the expressions (57) and (77) depend upon K , the action (75) approaches a limit independent of K for large values of K . In this limit, the metapopulation dynamics can be understood in terms of a stochastic dynamics of the fraction of occupied patches.

Such an approach was suggested by Lande et al. (1998). In the following we briefly describe the similarities and differences between our asymptotic result and the approach suggested by Lande et al. (1998). As already pointed out in the introduction, their analysis rests on four main assumptions: First, Lande et al. (1998) consider the limit of fast local dynamics and slow migration (time-scale separation). In our model, this corresponds to the limit $K \rightarrow \infty$ and to large values of r . Second, Lande et al. (1998) argue that the extinction rate in the stochastic model for the evolution of the number of occupied patches is given by the inverse time to extinction of a single patch, initially at carrying capacity. Third, it is assumed that the rate of successful colonisation is given by the product of the expected number of migrants and the probability that an empty patch invaded by one migrant grows to its (quasi-)steady state. Fourth, Lande et al. (1998) allow for the possibility that the number of individuals per patch in occupied patches changes as the metapopulation approaches extinction, and argue that this effect can be incorporated in terms of Q -dependent rates $c(Q)$ and $e(Q)$.

Here we have shown, however, that in the limit of small values of δ the dynamics of $\mathbf{f}$ on the most likely path to extinction is rigid: $\mathbf{f}$ does not change its shape, just its normalisation. This implies, in particular, that the average number of individuals on occupied patches must remain unchanged as extinction is approached. This is clearly seen in Fig. 10a. We note, however, that Fig. 10b shows that for larger values of δ , $\mathbf{f}$ does change its shape (and the average number of individuals in occupied patches decreases as extinction is approached). A first-principles theory for this effect is lacking. We refer to this point in the conclusions.

Let us now consider the parameterisations of the rates e and c suggested by Lande et al. (1998), Eqs. (3) and (4) in their paper. We have obtained analytical

results in the vicinity of the bifurcation (that is, for small values of δ). In order to compare our results to the choices adopted by Lande et al. (1998) we must take the limit $K \rightarrow \infty$. In this limit, it turns out, that the terms of order δ^3 (and higher) in the second and third rows of Eq. (48) are negligible compared to the terms in the first row. In the limit of large values of K we therefore conclude:

$$c = -(1 + \delta)a_{12} \quad \text{and} \quad e = c - a_{11}\delta. \quad (78)$$

The asymptotic expressions for a_{11} and a_{12} are given in Eq. (57). In appendix C we have shown that these relations correspond precisely to the asymptotic K -dependence of the time T_K to extinction for a single isolated patch at carrying capacity. In the limit of large K (which is the limit Lande et al. (1998) consider) we thus have:

$$e = \frac{1}{T_K}. \quad (79)$$

This equation implies that the rate of extinction of patches in the coupled system does not depend upon δ to leading order in δ . In other words, patches go extinct independently in the limit $K \rightarrow \infty$. Eq. (79) closely resembles Eq. (4) in (Lande et al., 1998).

Now consider the rate of successful colonisation. In the limit of $K \rightarrow \infty$, the probability of a single patch growing from one migrant to carrying capacity is $u_{1K} \sim (r - 1)/r$ (see appendix C). Immigration is irrelevant in this context since the local patch dynamics is assumed to be much faster than migration. Using this expression for u_{1K} and (38) for m_c we find the following expression for c

$$c = m_c(1 + \delta)Ku_{1K} = mKu_{1K}. \quad (80)$$

This result closely resembles Eq. (3) in (Lande et al., 1998). We emphasise that our results are exact in the limit of small values of δ and large values of N and K .

A further but minor difference is that Lande et al. (1998) employ the diffusion approximation to evaluate their Eqs. (3) and (4). This approximation fails unless r is close to unity.

We conclude this section with a discussion of Eq. (75). Eqs. (55,71) allow us to express the average time to extinction in the following form:

$$\log T_{\text{ext}} \sim \frac{N}{2}(-\mathbf{p}^{*\top})\mathbf{f}^* = \frac{N}{2} \sum_{j=1}^{\infty} (-p_j^*)f_j^*. \quad (81)$$

Here $\mathbf{f}^*$ is the quasi-steady state distribution, and the vector $-\mathbf{p}^{*\top}$ determines the susceptibility of patches with j individuals to stochastic fluctuations of the number

of individuals. As explained above, the components $-p_j^*$ are related to Fisher's reproductive vector characterising the susceptibility, for example, of age classes in matrix population-models. But note that in our case the components of $-\mathbf{p}^*$ do not characterise the properties of classes of individuals, but of patches. In other words, Eq. (81) can be understood by viewing the metapopulation as a population of patches, or as a population of local populations, as originally envisaged by Levins (1969).

3.2.4. *The limit of large emigration rates*

Most results presented in this paper concern metapopulation dynamics close to the critical line shown in the left panel of Fig. 3. The reason is that the metapopulation dynamics simplifies substantially in this regime, as shown in the preceding sections.

In this section we briefly discuss another limit of the metapopulation dynamics in the model introduced in Section 2, the limit of large emigration rates. This limit corresponds to the top part of the m - K plane shown in the left-most panel of Fig. 3. The limit is interesting for two reasons. First, in this limit too the metapopulation dynamics simplifies substantially. We show that the dynamics can be represented in terms of a one-dimensional process (just as Eq. (1) and the corresponding stochastic dynamics). But now the variable is the total number of individuals in the metapopulation and not Q_1 , or Q . Second, the results allow us to connect the subject and the results of the present paper to recent results by Higgins (2009).

In the limit of infinite emigration rate ($m \rightarrow \infty$) and no mortality during migration ($\zeta = 0$), the metapopulation behaves as a single large patch with modified birth and death rates that depend only on the total number of individuals in the metapopulation. This makes it possible to compute the average time to extinction exactly. This limit could describe, for example, biological populations in which larvae disperse randomly to all patches (e.g. pelagic marine species).

We start from the individual-based, stochastic metapopulation model introduced in Section 2, in the limit $\eta \rightarrow \infty$ and for $\zeta = 0$. There are N patches. It is convenient to characterise the state of the metapopulation by the number of individuals in each patch $i_1, \dots, i_N$ (rather than by the numbers f_j denoting the fraction of patches with j individuals as in the preceding sections). Since migration is infinitely faster than any other process, migration instantly brings the distribution of $i_1, \dots, i_N$ to multinomial form. Denoting the total number of individuals in the metapopulation by n , we see that after a birth ($n - 1 \rightarrow n$) or death ($n + 1 \rightarrow n$),

the distribution instantaneously relaxes to the multinomial distribution:

$$M_n(i_1, \dots, i_N) = \begin{cases} \frac{n!}{i_1! i_2! \dots i_N!} N^{-i_1} N^{-i_2} \dots N^{-i_N} & \text{if } \sum_{k=1}^N i_k = n, \\ 0 & \text{otherwise.} \end{cases} \quad (82)$$

We denote the birth and death rates for the whole metapopulation, conditional upon n , by B_n and D_n , respectively. These rates can be calculated by averaging the local birth and death rates, Eqs. (2) and (3), conditional upon n . For the birth rate we find

$$B_n = \left\langle \sum_{k=1}^N b_{i_k} \right\rangle = r \left\langle \sum_{k=1}^N i_k \right\rangle = rn, \quad (83)$$

by virtue of $\sum_{k=1}^N i_k = n$. For the death rate we find:

$$D_n = \sum_{i_1, \dots, i_N} \left(\sum_{k=1}^N d_{i_k} \right) M_n(i_1, \dots, i_N) = \mu n + \frac{r-\mu}{NK} n^2 + \frac{r-\mu}{K} n \left(1 - \frac{1}{N} \right). \quad (84)$$

These rates (we take $\mu = 1$ as before) define a one-dimensional, one-step birth-death process, that can be written in terms of a one-dimensional one-step master equation

$$\frac{d\rho_n}{dt} = (\mathbb{E}^- - 1)B_n\rho_n + (\mathbb{E}^+ - 1)D_n\rho_n, \quad (85)$$

for the probability $\rho_n(t)$ of finding n individuals in the metapopulation at time t . The raising and lowering operators in Eq. (85) are defined in analogy with Eq. (8): $\mathbb{E}^\pm g_n = g_{n\pm 1}$. The average time to extinction for the one-dimensional Eq. (85) can be obtained by recursion (the result is given in appendix C). For the case of the multi-dimensional master equation (10), by contrast, it was necessary to employ a large- N expansion before the dynamics could be reduced to the one-dimensional form (1) on the brink of extinction.

The results (83-85) allow us to investigate the question addressed by Higgins (2009), namely how the risk of extinction depends upon the degree of ‘fragmentation’ of a metapopulation, in the limit of infinite emigration rate. We define the total carrying capacity of the metapopulation $K_{\text{tot}} = KN$ and ask how the average time of extinction depends upon N , keeping K_{tot} constant. In other words, we fragment the metapopulation into N patches of equal size, such that the total carrying capacity remains the same. Figure 14 shows how the average time to extinction depends on the degree of fragmentation, for three different values of K_{tot} (100, 500, and 1000), for $r = 1.01$ (other parameter values give qualitatively

similar results). The initial number of individuals is taken to be $5K_{\text{tot}}$ (the average time to extinction depends only weakly on the initial number of individuals, provided this number is larger than K_{tot}). The analytical results (lines) are in good agreement with results, for large emigration rates, of direct numerical simulations of the model introduced in Section 2. Results are shown for two values of the emigration rate, $m = 1$ and 10 . Each data point (symbols in Fig. 14) is estimated from 100 independent simulations.

We find that the time to extinction decreases monotonically as the degree of fragmentation increases. For small degrees of fragmentation, the time to extinction is approximately independent of the number of patches, but for larger levels of fragmentation, the time to extinction decreases markedly as fragmentation increases. Since the time to extinction is approximately exponentially distributed, this implies that the probability of extinction during a given time span increases monotonically as the metapopulation becomes more and more fragmented.

This result is in qualitative agreement with the findings of Higgins (2009) for intermediate and large degrees of fragmentation. By contrast, when the number of patches is small, Higgins (2009) observes a decrease in the extinction risk with increasing fragmentation. A possible reason for this difference is that Higgins (2009) considers local environmental fluctuations that would increase the local rate of extinction compared to demographic fluctuations alone (Melbourne and Hastings, 2008). This could be important when the number of patches is low, but when the number of patches is large the fluctuations are averaged over and may become less important.

4. Conclusions

In this paper we have analysed metapopulation dynamics on the brink of extinction in terms of a stochastic, individual-based metapopulation model consisting of a finite number N of patches. In our model the distance from the bifurcation point where infinitely large metapopulations cease to persist is parameterised by the parameter δ . It measures the difference in emigration rate to its critical value at the bifurcation point. In the limit of large (but finite) values of N and small values of δ we have been able to quantitatively describe the stochastic metapopulation dynamics. We have shown that metapopulation dynamics, for small values of δ , is described by a one-dimensional equation of the form of Levins' model, Eq. (1). We have derived explicit expressions for the parameters c and e in terms of the parameters describing the local population dynamics, and migration. We have shown that Levins' model is valid independently of whether or not there

is a time-scale separation between local and migration dynamics. The crucial condition is that the metapopulation is close to extinction. We note that in the absence of time-scale separation, the interpretation of the variable Q in Eq. (1) is no longer the fraction of occupied patches. More precisely, Q corresponds to the fraction of occupied patches if the growth rates and local carrying capacities are large enough; otherwise it has a different meaning, in particular, for small growth rates and carrying capacities it approximately corresponds to the average number of individuals per patch.

The deterministic limit of our model corresponds to metapopulation models discussed by Casagrandi and Gatto (2002) and Nachman (2000), who have studied the persistence of infinitely large metapopulations by analysing the stability of steady states. The corresponding persistence criteria (which we discuss in detail) do not allow to characterise the persistence of finite metapopulations. By contrast, the stochastic dynamics derived and analysed in this paper makes it possible to characterise the most likely path to extinction and to estimate the average time to extinction of the metapopulation. We have discussed differences and similarities between a particular asymptotic limit of our results, and the results obtained by Lande et al. (1998). Fig. 15 summarises different limiting cases of our results, and connections to earlier studies.

While our approach results in a comprehensive description of metapopulation dynamics for the model we consider, many open questions remain. A technical point is that we have not yet been able to compute the pre-factor A in the expression (74) for the average time to extinction. This is a difficult problem requiring matching the solutions found in this paper with corresponding solutions valid for small values n_j (the number of patches with j individuals). Such solutions are outside the scope of our large- N treatment.

Many results derived in this paper are valid close to the critical line in Fig. 3, that is on the brink of extinction. The reason is that the metapopulation dynamics simplifies considerably in this regime, as we have shown in this paper. Further work is required in order to understand metapopulation dynamics for emigration rates much larger than the critical value. In this case, especially when the number of migrants is large, we have observed deviations from Levins' model: the shape of the distribution of local patch population sizes is no longer rigid on the path to extinction. Biologically this reflects, for example, the rescue effect, whereby immigration from colonised patches extends the time to local extinction. A quantitative theory of this effect based on the life history of the individuals in the metapopulations is currently lacking.

There is, however, a second limit of our individual-based, stochastic metapop-

ulation model that can be analysed in a simple fashion. This is the limit of very large emigration rates, $m \rightarrow \infty$, where the metapopulation is well mixed, so that, in the absence of mortality during migration, it can be modelled as a single large patch. In this limit it is possible to analyse the question posed by Higgins (2009), namely how the risk of extinction of a metapopulation depends on the degree of its fragmentation. In the limit of large emigration rates, we have derived the expected time to extinction for our individual-based stochastic metapopulation model. We find that the time to extinction decreases as the degree of fragmentation of the population increases. There is excellent agreement between this prediction and results of direct numerical simulations of the model introduced in Section 2, for large but finite emigration rates. For highly fragmented populations, our conclusions are consistent with the results of Higgins (2009). When the number of patches is small, by contrast, Higgins (2009) observes a different behaviour (discussed in Sec. 3.2.4). A possible reason for this difference is that Higgins (2009) considers local environmental fluctuations. These would increase the local rate of extinction compared to demographic fluctuations alone (Melbourne and Hastings, 2008). This could be important when the number of patches is low. But when the number of patches is large the fluctuations are averaged over and are thus expected to be less important. To understand the differences and similarities between the models (and their biological implications) requires further work.

The approach described in this paper allows us to address many other important questions in metapopulation dynamics. Consider for example the dynamics of structured metapopulations. Core-satellite models (Hanski and Gyllenberg, 1993) of metapopulations have two types of patches, large and small. Large patches have more persistent populations, while populations in smaller patches are relatively ephemeral. Thus, the large patches are, on average, sources and the small patches are sinks for the metapopulation as a whole. Such models can be treated by suitable generalisations of the approach described in the present paper.

Another important question is the role of environmental fluctuations. The within-patch population dynamics in our model takes demographic fluctuations into account, but does not explicitly incorporate the effect of local environmental fluctuations. Such fluctuations may be due to, for example, yearly fluctuations in growth rates, mortality, or carrying capacity (Melbourne and Hastings, 2008). The environmental fluctuations may be local, affecting patches independently. Alternatively the fluctuations of the rates may be global, that is, the same for all patches (or at least highly correlated).

What is the effect of local environmental fluctuations? Consider the set of patches with j individuals. One may expect that, when the number of patches is

large, only average rates enter into the deterministic equations of motion (16). But the environmental noise gives rise to fluctuations, and therefore leads to shorter persistence times of individual patches. This in turn implies higher patch turnover (Melbourne and Hastings, 2008).

When the patches are few, the destabilising effect of local environmental fluctuations on patches can significantly affect the time to extinction (Higgins, 2009). The tendency of local environmental fluctuations to increase patch turnover could be represented in our model by introducing a separate process to the local population dynamics, whereby patches go extinct at a fixed rate, independently of the local population size, for example in terms of the ‘killing’ process (Coolen-Schrijner and van Doorn, 2006). The theory outlined in this paper then makes it possible to determine the effect of this process upon the time to extinction of the metapopulations.

Global environmental fluctuations, affecting all patches simultaneously, can be incorporated in our model by introducing a time-dependent contribution $\delta\mu(t)$ to the death rate in Eq. (3), the same for all patches. Taking this to be a random piecewise-constant function of time makes it possible to employ the approach described by Schaper et al. (2012).

Last but not least, it is necessary to compare the predictions summarised here with those of models with an explicit spatial structure. We expect that the predictions summarised here should be the more accurate the wider the spatial scale of migration is.

Appendix A Formulae for the matrix elements occurring in the expansion of the master equation

The matrix $\mathbf{D}(\mathbf{f})$ (see Eq. (26)) has entries

$$\begin{aligned}
 D_{ij} = & \delta_{ij} \left((b_{i-1} + I) f_{i-1} + (d_{i+1} + m_{i+1}) f_{i+1} + (b_i + I + d_i + m_i) f_i \right) \\
 & + \delta_{i+1j} \left(- (d_{i+1} + m_{i+1}) f_{i+1} - (b_i + I) f_i \right) \\
 & + \delta_{i-1j} \left(- (b_{i-1} + I) f_{i-1} - (d_i + m_i) f_i \right) \\
 & + m_{i+1} f_{i+1} (f_{j-1} - f_j) + f_i (m_j f_j - m_{j+1} f_{j+1}) \\
 & + m_i f_i (f_j - f_{j-1}) + f_{i-1} (m_{j+1} f_{j+1} - m_j f_j) \quad \text{for } i, j > 1,
 \end{aligned} \tag{A.1}$$

$$\begin{aligned}
 D_{1j} = & \delta_{j2} \left(- (d_2 + m_2) f_2 - (b_1 + I) f_1 \right) + m_2 f_2 (f_{j-1} - f_j) + m_1 f_1 (f_j - f_{j-1}) \\
 & + f_1 (m_j f_j - m_{j+1} f_{j+1}) + \left(1 - \sum_{k=1}^{\infty} f_k \right) (m_{j+1} f_{j+1} - m_j f_j) \quad \text{for } j > 1,
 \end{aligned}$$

$$\begin{aligned}
 D_{i1} = & \delta_{i2} \left(- (d_2 + m_2) f_2 - (b_1 + I) f_1 \right) + m_2 f_2 (f_{i-1} - f_i) + m_1 f_1 (f_i - f_{i-1}) \\
 & + f_1 (m_i f_i - m_{i+1} f_{i+1}) + \left(1 - \sum_{k=1}^{\infty} f_k \right) (m_{i+1} f_{i+1} - m_i f_i) \quad \text{for } i > 1,
 \end{aligned}$$

$$\begin{aligned}
 D_{11} = & I \left(1 - \sum_{k=1}^{\infty} f_k \right) + (d_2 + m_2) f_2 + (b_1 + I + d_1 + m_1) f_1 \\
 & + 2 \left(1 - \sum_{k=1}^{\infty} f_k - f_1 \right) (m_2 f_2 - m_1 f_1).
 \end{aligned}$$

The elements of $\mathbf{A}$ (see Eq. (27)) are given by

$$\begin{aligned}
 A_{ij} = & (b_{i-1} + I) \delta_{i-1j} + (d_{i+1} + m_{i+1}) \delta_{i+1j} - (b_i + I + d_i + m_i) \delta_{ij} \\
 & + m_j (f_{i-1} - f_i) \quad \text{for } i > 1,
 \end{aligned} \tag{A.2}$$

$$A_{1j} = (d_2 + m_2) \delta_{j2} - (b_1 + I + d_1 + m_1) \delta_{j1} - I + m_j \left(1 - \sum_{k=1}^{\infty} f_k - f_1 \right).$$

The elements of $\mathbf{A}^{(0)}$ in the expansion (41) are obtained by setting $\delta = 0$ in Eq. (A.2). The elements of $\mathbf{A}^{(1)}$ occurring in the same expansion are found to be:

$$A_{ij}^{(1)} = \begin{cases} j(\delta_{i+1j} - \delta_{ij}) & \text{for } i > 1 \\ j(\delta_{j2} - \delta_{j1} + 1) & \text{for } i = 1 \end{cases}. \tag{A.3}$$

Finally, the coefficients $A_{ijk}^{(2)}$, also appearing in the expansion (41), are given by:

$$A_{ijk}^{(2)} = \begin{cases} -k(\delta_{ij} - \delta_{i-1j}) - j(\delta_{ik} - \delta_{i-1k}) & \text{for } i > 1 \\ -k(\delta_{1j} + 1) - j(\delta_{1k} + 1) & \text{for } i = 1 \end{cases} \quad (\text{A.4})$$

The coefficients $B_{ijk}^{(1)}$ (see Eq. (64)) are given by:

$$\begin{aligned} B_{ijk}^{(1)} &= b_k[\delta_{ki-1}(\delta_{ij} - \delta_{ji-1}) + \delta_{ik}(\delta_{ij} - \delta_{ji+1})] \\ &\quad + (d_k + m_k)[\delta_{ki+1}(\delta_{ij} - \delta_{ji+1}) + \delta_{ik}(\delta_{ij} - \delta_{ji-1})] \quad \text{for } i, j > 1, \\ B_{1jk}^{(1)} &= (d_2 + m_2)(-\delta_{k2}\delta_{j2}) - b_1\delta_{k1}\delta_{j2} + m_k(\delta_{kj+1} - \delta_{kj}) \quad \text{for } j > 1, \\ B_{i1k}^{(1)} &= (d_2 + m_2)(-\delta_{k2}\delta_{i2}) - b_1\delta_{k1}\delta_{i2} + m_k(\delta_{ki+1} - \delta_{ki}) \quad \text{for } i > 1, \\ B_{11k}^{(1)} &= m_k + (d_2 + 3m_2)\delta_{k2} + (b_1 + d_1 - m_1)\delta_{k1}. \end{aligned} \quad (\text{A.5})$$

Appendix B Summary of results for coefficients used in section 3

In this appendix we give explicit expressions for the coefficients I_1 , c_1 , c_2 , a_{11} , a_{12} and b_{12} appearing in Eqs. (36), (39), (40), (49), and (65). First, the coefficient I_1 in Eq. (36) is calculated by expanding Eq. (33). Expanding to lowest order yields the condition (37) which gives m_c but does not determine I_1 . In order to find I_1 it is necessary to expand Eq. (33) to second order in δ . This requires expanding:

$$\begin{aligned} m_c(1 + \delta) \sum_{j=2}^{\infty} j \prod_{k=2}^j \frac{b_{k-1} + I^*}{d_k + m_c k} &= I_1 \delta - I_2 \delta^2 + g_1(I_1) \delta^2 + \dots, \\ \sum_{j=2}^{\infty} \prod_{k=2}^j \frac{b_{k-1} + I^*}{d_k + m_c k} &= g_0(I_1) \delta + \dots \end{aligned} \quad (\text{B.1})$$

We find:

$$g_0(I_1) = \frac{I_1}{d_1 + m_c} \left(1 + \sum_{j=2}^{\infty} \frac{R_{1j}}{R_{11}} \right) \quad (\text{B.2})$$

$$\begin{aligned} g_1(I_1) &= \frac{d_1}{d_1 + m_c} I_1 - \frac{m_c I_1}{d_1 + m_c} \sum_{k=2}^{\infty} \frac{k R_{1k}}{R_{11}} \sum_{i=2}^k \frac{m_c i}{d_i + m_c i} \\ &\quad + \frac{m_c I_1^2}{d_1 + m_c} \sum_{k=2}^{\infty} \frac{k R_{1k}}{R_{11}} \sum_{i=2}^k \frac{1}{b_{i-1}}. \end{aligned} \quad (\text{B.3})$$

Inserting these expansions into the self-consistency condition (33) gives:

$$I_1 = \frac{g_1(I_1)}{g_0(I_1)}. \quad (\text{B.4})$$

We find

$$I_1 = \frac{d_1 - m_c \sum_{k=2}^{\infty} \frac{k R_{1k}}{R_{11}} \sum_{i=2}^k \frac{m_c i}{d_i + m_c i}}{1 + \sum_{k=2}^{\infty} \frac{R_{1k}}{R_{11}} (1 - k \sum_{i=2}^k \frac{1}{b_{i-1}})}. \quad (\text{B.5})$$

Second, the coefficient c_1 determines the leading order of the δ -expansion of the fraction f_0^* of extinct patches in the steady state. To leading order in δ we have $f_0^*(\delta) \sim 1 - g_0(\delta)$. Thus the coefficient c_1 in Eq. (39) is given by

$$c_1 = \frac{I_1}{d_1 + m_c} \left(1 + \sum_{j=2}^{\infty} \frac{R_{1j}}{R_{11}} \right). \quad (\text{B.6})$$

Third, the coefficient c_2 determining the lowest order of an expansion of the number of individuals per patch, Eq. (40), in powers of δ is given by the lowest-order term of Eq. (B.1). We find:

$$c_2 = \frac{I_1}{m_c}. \quad (\text{B.7})$$

Fourth, in order to find the coefficients a_{11} and a_{12} appearing in Eq. (49), we insert Eqs. (A.4) and (A.3) into Eq. (47) for $\alpha = 1$. Using Eqs. (50) and (52) yields

$$a_{11} = L_{11} R_{11} \left(d_1 - m_c \sum_{k=2}^{\infty} \frac{k R_{1k}}{R_{11}} \sum_{j=2}^k \frac{m_c j}{d_j + m_c j} \right), \quad (\text{B.8})$$

$$a_{12} = - (d_1 + m_c) L_{11} R_{11}^2 \left(1 + \sum_{k=2}^{\infty} \frac{R_{1k}}{R_{11}} \left(1 - k \sum_{j=2}^k \frac{m_c}{b_{j-1}} \right) \right). \quad (\text{B.9})$$

Finally, the coefficient b_{11} in Eq. (65) is determined by inserting Eq. (A.1) into Eq. (66), which results in

$$b_{11} = \sum_{i=2}^{\infty} (d_i + m_c i) (L_{1i} - L_{1i-1})^2 R_{1i} - L_{11} \sum_{i=2}^{\infty} m_c i (L_{1i} - L_{1i-1}) R_{1i} + d_1 L_{11}^2 R_{11}. \quad (\text{B.10})$$

Appendix C Asymptotics for large values of K

In this appendix we briefly demonstrate how to obtain the asymptotics of the eigenvectors, of the coefficients a_{11} , a_{12} , b_{12} , and of the critical emigration rate m_c in the limit of $K \rightarrow \infty$ (see Eqs. (38) (57), and (77) in the main text). First, the results of this appendix demonstrate that the action (75) tends to $1/2$ as $K \rightarrow \infty$. Second, the results obtained below shed light on the connection of our results to the work of Lande et al. (1998).

In the limit of large carrying capacities K , the asymptotics of the coefficients a_{11} , a_{12} , b_{12} is given by the asymptotics of R_{11} which in turn is determined by the requirement that $\mathbf{L}_1^\top \mathbf{R}_1 = 1$. The first step consists of deriving the asymptotic form of m_c , Eq. (38), in the limit of $K \rightarrow \infty$. The critical emigration rate m_c is given by Eq. (37):

$$d_1 = m_c \sum_{j=2}^{\infty} j \prod_{k=2}^j \frac{b_{k-1}}{d_k + m_c k}. \quad (\text{C.1})$$

The product in this equation is estimated by exponentiation, taking the continuum limit, and the resulting integral is evaluated in the saddle-point approximation, exactly as described by Doering et al. (2005), see also (Mehlig and Wilkinson, 2007). Following Doering et al. (2005) we introduce the variable $x = i/K$ and define the functions $b(x)$ and $d(x)$ by

$$b_i = K b(x) \quad \text{and} \quad d_i = K d(x). \quad (\text{C.2})$$

In the limit of $K \rightarrow \infty$, the term $m_c k$ in the denominator in (C.1) is negligible compared to d_k . The product is then estimated using

$$\prod_{k=1}^{j-1} \frac{b_k}{d_k} \sim e^{K \int_0^y dx \log \rho(x) - \frac{1}{2} [\log \rho(0) + \log \rho(y)]} = \frac{e^{-K\Phi(y)}}{\sqrt{\rho(0)\rho(y)}} \quad (\text{C.3})$$

with $y = j/K$, $\rho(x) = b(x)/d(x)$, and

$$\Phi(y) = - \int_0^y dx \log \rho(x) = - \int_0^y \frac{dx r}{1 + (r-1)x}. \quad (\text{C.4})$$

It follows that

$$\sum_{j=2}^{\infty} d_1 \frac{j}{d_j} \prod_{k=1}^{j-1} \frac{b_k}{d_k} \sim K^2 \int_0^{\infty} dy \frac{d_1}{d(y)} \frac{e^{-K\Phi(y)}}{\sqrt{\rho(0)\rho(y)}}. \quad (\text{C.5})$$

The integral is evaluated in the saddle-point approximation. The saddle point is $x_s = 1$. With $d^2\Phi/dx^2 = (r-1)/r$ at $x_s = 1$ we have:

$$\sum_{j=2}^{\infty} \frac{d_1}{d_j} \prod_{k=1}^{j-1} \frac{b_k}{d_k} \sim K^2 \sqrt{\frac{2\pi r}{K(r-1)}} \frac{1}{Kr} \frac{1}{\sqrt{r}} e^{\left[K \left(1 - \frac{\log r}{r-1} \right) \right]}, \quad (\text{C.6})$$

resulting in Eq. (38).

The second step consists of determining the limiting form (53) of the elements of $\mathbf{L}_1$, Eq. (52), in the limit of large values of K . We now show that the double sum in Eq. (52) grows exponentially, precisely cancelling the exponential decrease of m_c as $K \rightarrow \infty$. The calculation is very closely related to the evaluation of the time to extinction in a single-patch model by Doering et al. (2005). We use

$$\sum_{n=2}^{j-1} \sum_{k=n+1}^{\infty} \frac{kR_{1k}}{nR_{1n}} \sim \frac{K^2}{Kr} \sqrt{\frac{2\pi r}{K(r-1)}} e^{\left[K \left(1 - \frac{\log r}{r-1} \right) \right]} \sum_{n=2}^{j-1} \sqrt{\rho(0)} e^{-n \log r}. \quad (\text{C.7})$$

Performing the geometric sum and inserting the result into Eq. (52) we obtain

$$L_{1j} = 1 - r^{-j}. \quad (\text{C.8})$$

The third step consists of estimating R_{11} which is determined by the requirement

$$1 = \mathbf{L}_1^\top \mathbf{R}_1 \sim R_{11} \left(\frac{r-1}{r} + \sum_{j=2}^{\infty} (1-r^{-j}) \frac{d_1}{d_j} \prod_{k=1}^{j-1} \frac{b_k}{d_k} \right). \quad (\text{C.9})$$

We proceed as before and find:

$$R_{11} \sim r \sqrt{\frac{K(r-1)}{2\pi}} e^{\left[-K \left(1 - \frac{\log r}{r-1} \right) \right]}. \quad (\text{C.10})$$

These results enable us to determine the coefficients a_{11} , a_{12} , b_{12} from Eqs. (B.8) to (B.10). In Eq. (B.8), the double sum is negligible compared to d_1 in the limit of $K \rightarrow \infty$. This implies

$$a_{11} \sim L_{11} R_{11} d_1 \sim \sqrt{\frac{K(r-1)^3}{2\pi}} e^{\left[-K \left(1 - \frac{\log r}{r-1} \right) \right]}. \quad (\text{C.11})$$

In Eq. (B.9), the sum over j is negligible compare to unity. Evaluating the sum over k in the asymptotic limit, we find:

$$a_{12} \sim - \sqrt{\frac{K(r-1)^3}{2\pi}} e^{\left[-K \left(1 - \frac{\log r}{r-1} \right) \right]}. \quad (\text{C.12})$$

Finally, Eq. (B.10) consists of three terms. The second term is negligible compared to the other two. This implies:

$$b_{11} \sim \sqrt{\frac{K(r-1)^3}{2\pi}} e^{\left[-K\left(1-\frac{\log r}{r-1}\right)\right]}. \quad (\text{C.13})$$

We see that the three coefficients have the same asymptotic dependence on K , apart from the minus sign in Eq. (C.12). It turns out that this asymptotic K -dependence is exactly the inverse of the asymptotic dependence of the average time to extinction T_K upon K for a single isolated patch with rates given by Eqs. (2,3) at carrying capacity K (no migration). The exact expression for the average time to extinction starting with i individuals is (Nisbet and Gurney, 1982; van Kampen, 1981; Doering et al., 2005)

$$T_i = \sum_{n=1}^{\infty} \frac{1}{d_n} \prod_{k=1}^{n-1} \frac{b_k}{d_k} + \sum_{n=1}^{i-1} \prod_{k=1}^i \frac{d_k}{b_k} \sum_{j=n+1}^{\infty} \frac{1}{d_j} \prod_{k=1}^{j-1} \frac{b_k}{d_k}. \quad (\text{C.14})$$

The corresponding asymptotic expression for $i = K$ and large values of K is given in Eq. (19) of Doering et al. (2005):

$$T_K = \sqrt{\frac{2\pi}{K(r-1)^3}} e^{\left[K\left(1-\frac{\log r}{r-1}\right)\right]}. \quad (\text{C.15})$$

Last but not least let us consider the probability u_{1K} that a single isolated patch grows from one individual to its carrying capacity K . According to van Kampen (1981) one has:

$$u_{1K} = \left(1 + \sum_{i=1}^{K-1} \prod_{j=1}^i \frac{d_j}{b_j}\right)^{-1}. \quad (\text{C.16})$$

This expression becomes independent of K in the limit $K \rightarrow \infty$. Following the same procedure as above, we find in this limit:

$$u_{1K} \sim \frac{r-1}{r}. \quad (\text{C.17})$$

The corresponding probability to grow from j individuals to K is (van Kampen, 1981):

$$u_{jK} = \frac{1 + \sum_{i=1}^{j-1} \prod_{k=1}^i \frac{d_k}{b_k}}{1 + \sum_{i=1}^{K-1} \prod_{k=1}^i \frac{d_k}{b_k}}, \quad (\text{C.18})$$

This expression tends to

$$u_{jK} \sim 1 - r^{-j} \quad (\text{C.19})$$

as $K \rightarrow \infty$.

Table 1: Symbols used in this article

Symbol	Explanation
Q	Fraction of occupied patches, Eq. (1)
c	Colonisation rate, Eq. (1)
e	Extinction rate, Eq. (1)
N	Number of patches, Sec. 2.1
r, μ	Per-capita birth and death rates, Eqs. (2,3)
K	Patch carrying capacity, Eq. (3)
m	Per capita emigration rate, Eq. (4)
b_i, d_i, m_i	Birth-, death- and emigration rates for patch with i individuals, Eqs. (2,3,4)
I	Patch immigration rate, Sec. 2.1
M	Number of migrants in common migration pool, Sec. 2.1
η	Rate at which migrants leave common migration pool, Sec. 2.1
ζ	Rate of mortality during migration, Sec. 2.1
Λ_k	Rate for next event generated in patch k , Sec. 2.2
Λ	Rate for next event occurring in population, Sec. 2.2
$\mathbf{n}$	$\mathbf{n} = (n_1, n_2, \dots)^T$ where n_i is number of patches with i individuals, Sec. 2.3
$\rho(\mathbf{n}, t)$	Probability of finding metapopulation in state $\mathbf{n}$ at time t , Eq. (10)
$\mathbb{E}_j^\pm$	Raising and lowering operators, Eq. (8)
δ_{ij}	Kronecker delta: $\delta_{ij} = 1$ if $i = j$, and $\delta_{ij} = 0$ if $i \neq j$, Sec. 2.3
$\mathbf{f}$	$\mathbf{f} = \mathbf{n}/N$: f_i is fraction of patches with i individuals, Sec. 2.4
$\tilde{\rho}(\mathbf{f}, t)$	$\tilde{\rho}(\mathbf{f}, t) = \rho(\mathbf{n}, t)$, Eq. (15) (from Sec. 2.4.1 onwards, the tilde is dropped to simplify the notation)
$\mathbf{v}(\mathbf{f})$	Right-hand side of deterministic equation for $\mathbf{f}$, Eq. (16)
$S(\mathbf{f})$	Action, Eq. (19)
$\mathbf{p}$	$\mathbf{p} = (p_1, p_2, \dots)^T$: $p_i = \partial S / \partial f_i$, Sec. 2.4.2
$H(\mathbf{f}, \mathbf{p})$	Hamiltonian function, Eq. (21)
$\mathbf{A}$	Jacobian matrix of the function $\mathbf{v}(\mathbf{f})$: $A_{ij} = \partial v_i / \partial f_j$, Sec. 2.4.2
$\mathbf{D}$	Matrix with elements $D_{ij} = \partial^2 H / \partial p_i \partial p_j$, Eq. (26)
$\mathbf{J}$	Jacobian matrix of the Hamiltonian dynamics, Eq. (27)
$\mathbf{C}$	Covariance matrix (multiplied by N): $C_{ij} = N \text{cov}[f_i, f_j]$, Eq. (31)
σ_j^2	Variance of f_j : for $j \geq 1$: $\sigma_j^2 = C_{jj}/N$, Sec. 3.2.1
$\mathbf{f}^*$	$\mathbf{f}$ at (quasi-)steady state, Eq. (32)

Continued on next page...

Table 1 (continued): Symbols used in this article

Symbol	Explanation
$\delta \mathbf{f}, \delta \mathbf{p}$	Disturbance of $\mathbf{f}$ and $\mathbf{p}$ away from $(\mathbf{f}^*, \mathbf{0})$, Eq. (30)
I^*	Immigration rate at (quasi-)steady state, Eq. (33)
$\mathbf{p}^*$	$\mathbf{p}$ at the fluctuational extinction point, Eq. (59)
m_c	Critical emigration rate, Eq. (34)
δ	$\delta = (m - m_c)/m_c$, Eq. (35)
$\mathbf{A}^{(0)}$	$\mathbf{A}$ evaluated at $\delta = 0$, Eq. (41)
$\mathbf{A}^{(1)}$	Matrix with elements $A_{ij}^{(1)} = \partial^2 v_i / \partial f_j \partial m$, evaluated at $\delta = 0$, Eq. (41)
$A_{ijk}^{(2)}$	$A_{ijk}^{(2)} = \partial^3 v_i / \partial f_j \partial f_k \partial m$, evaluated at $\delta = 0$, Eq. (41)
λ_α	Eigenvalues of $\mathbf{A}$, ordered such that $\lambda_1 > \lambda_2 \geq \lambda_3 \geq \dots$, Eq. (43)
$\lambda_\alpha^{(0)}$	Eigenvalues of $\mathbf{A}^{(0)}$, Eq. (43)
$\mathbf{L}_\alpha, \mathbf{R}_\alpha$	Left and right eigenvectors of $\mathbf{A}^{(0)}$ with eigenvalues $\lambda_\alpha^{(0)}$, Eq. (43)
$\mathbf{J}^{(0)}$	$\mathbf{J}$ evaluated at $\delta = 0$, Eq. (60)
$\mathcal{R}_\alpha, \mathcal{R}'_\alpha$	Right eigenvectors of $\mathbf{J}^{(0)}$, with eigenvalues $\lambda_\alpha^{(0)}$ and $-\lambda_\alpha^{(0)}$, Eq. (61)
$\mathcal{L}_\alpha, \mathcal{L}'_\alpha$	Left eigenvectors of $\mathbf{J}^{(0)}$, with eigenvalues $\lambda_\alpha^{(0)}$ and $-\lambda_\alpha^{(0)}$, Eq. (62)
Q_α	Slow ($\alpha = 1$) and fast ($\alpha > 1$) components of deterministic dynamics for $\mathbf{f}$, Eq. (44)
P_α	Slow ($\alpha = 1$) and fast ($\alpha > 1$) momenta of the Hamiltonian dynamics, Eq. (63)
$B_{ijk}^{(1)}$	$B_{ijk}^{(1)} = \partial D_{ij} / \partial f_k$, Sec. 3.2.2
a_{11}, a_{12}, b_{11}	Coefficients in Eqs. (48,65)
Q_1^*	Slow variable Q_1 at (quasi-)steady state, Eqs. (55,70)
P_1^*	Slow variable P_1 at fluctuational extinction point, Eqs. (69,71)
T_{ext}	Expected time to extinction of the metapopulation, Eq. (74)
T_K	Expected time to extinction of a single patch, Sec. 3.2.3
u_{jK}	Probability that patch with j individuals reaches K individuals before becoming extinct, Eq. (80)
n	Total number of individuals in metapopulation, Sec. 3.2.4
$M_n(i_1, \dots, i_N)$	Multinomial distribution of $i_1, \dots, i_N$, with $\sum_{k=1}^N i_k = n$, Eq. (82)
B_n, D_n	Global birth and death rates in the limit $m \rightarrow \infty$, Eqs. (83, 84)
K_{tot}	Global carrying capacity in the limit $m \rightarrow \infty$, Sec. 3.2.4

Figures

Figure 1: Illustrates the stochastic, individual-based metapopulation model. The model describes N local populations (also referred to as patches). The number of individuals in patch k is denoted by i_k . Individuals are born and die with per-capita rates b_{i_k} and d_{i_k} . Furthermore, individuals may emigrate to a common dispersal pool (emigration rate m) where they stay an exponentially distributed time (with rate η) before leaving the pool for one of the N patches. Migration may fail if the individuals die before reaching the new patch, this possibility is modelled by introducing a death rate ζ during dispersal. The instantaneous number of migrants in the pool is denoted by M . The immigration rate from the dispersal pool into any given patch is given by $I = \eta M/N$.

Figure 2: Illustrates the WKB method. **(a)** Schematic plot of the f - p plane. The significance of the variables f and p is explained in Section 2.4 The deterministic dynamics, Eq. (16), corresponds to motion along the f -axis. The form of the action $S(f)$, Eq. (25), is determined by the path from the quasi-steady state $(f^*, 0)$ to the fluctuational extinction point $(0, p^*)$, corresponding to the most likely path to extinction. This is a standard situation, often referred to in the literature. See for example Fig. 1 in Box 3 in (Ovaskainen and Meerson, 2010). **(b)** Schematic. Shows $S(f)$ as a function of f (solid line). Also shown (dashed line) is a quadratic approximation of $S(f)$. This illustrates that the quasi-steady state distribution $\rho(f)$ is Gaussian close to f^* , but in general non-Gaussian in the tails.

Figure 3: Left: critical emigration rate m_c in the limit of infinitely many patches, $N \rightarrow \infty$, as a function of the carrying capacity K (solid line), computed from Eq. (37). The growth rate is $r = 1.05$. Above this critical line, metapopulations persist in the limit of $N \rightarrow \infty$. Right: six different stable steady states $\mathbf{f}^*$, obtained by solving Eqs. (32, 33) numerically, for $r = 1.05$, and for the values of the emigration rate m and K indicated in the left panel.

Figure 4: **(a)** Average number of individuals per patch $\sum_{j=1}^{\infty} j f_j$ in the quasi-steady state as a function of the emigration rate m for three different values of the carrying capacity K . Shown are numerical solutions of Eqs. (16,18), solid lines. Labels indicate the corresponding values of K . The growth rate is $r = 1.05$. Curves corresponding to the asymptotic expression (40), valid as m approaches the critical migration rate m_c , are shown as dashed lines. Also shown are results of direct numerical simulations as described in section 2.2 for metapopulations consisting of $N = 1000$ ($\triangle$), $N = 100$ ($\square$), and $N = 50$ ($\circ$) patches. **(b)** Same but the fraction of occupied patches $1 - f_0^*$ as a function of m . The asymptotic behaviour as $m \rightarrow m_c$ is given by Eq. (39) (dashed lines). The results for the direct simulations are obtained as follows. For each set of parameters, 30 stochastic runs up to a time smaller than the expected time to extinction are performed (if extinction occurs, the simulation is discarded). After the initial transient, 20 samples are taken from each simulation (separated by a time long enough so that the samples are uncorrelated). If the simulations consistently become extinct during the initial transient we conclude that there is no quasi-steady state, and f_0^* is set to unity.

Figure 5: **(a)** Average number of individuals per patch $\sum_{j=1}^{\infty} j f_j$ as a function of time for $r = 1.05$, $K = 50$, and $m = 0.0167$. Shown are numerical solutions of Eqs. (16,18) for three different initial conditions: ten individuals per patch, 26 individuals per patch, and 50 individuals per patch as indicated by labels in the figure. Also shown are results of direct simulations as described in section 2.2, for $N = 1000$ ($\triangle$), $N = 100$ ($\square$) and $N = 50$ ($\circ$), for each of the three initial conditions. The steady-state value is shown as a dashed line. **(b)** Same, but the frequency of empty patches f_0 as a function of time. Each point of the direct simulations corresponds to an average over 100 stochastic realisations conditional on no extinction (no extinction actually occurred during these simulations).

Figure 6: Deterministic relaxation towards the stable steady state f^* . **(a)** Average number of individuals per patch, $\sum_{j=1}^{\infty} j f_j$, as a function of time for $r = 1.05$, $K = 50$, and $\delta = 0.05$. Shown as solid lines are numerical solutions of Eqs. (16,18) for three different initial conditions (indicated by labels in the figure): five individuals per patch, one individual per patch, and 10^{-3} individuals per patch on average. Also shown are solutions of Eqs. (46) and (49) (dashed lines). **(b)** Same, but the frequency of empty patches f_0 as a function of time.

Figure 7: Shows the components L_{1j} of the left eigenvector $\mathbf{L}_1$ (see Eq. (43)) as a function of j , for $r = 1.5$, $K = 50$, and for $r = 1.05$, $K = 10$ (solid lines). The dashed line corresponds to the limit $K \rightarrow \infty$, Eq. (54), evaluated for $r = 1.5$.

Figure 8: Size of the fluctuations around the quasi-steady state of the distribution (19). **(a)** Standard deviation σ_0 of the fraction of empty patches as a function of the number of patches N . Comparison of σ_0 , calculated from $\mathbf{C}$ in Eq. (31) and employing Eq. (58) (solid line), to direct numerical simulations ($\circ$). Parameters: $r = 1.05$, $K = 50$, $m = 0.02$. **(b)** Variances σ_j^2 of the fraction of patches f_j with j individuals as a function of j ($j = 1, 2, \dots$). Comparison of σ_j^2 calculated using Eq. (31) (solid line), to direct numerical simulations ($\circ$) for $N = 100$. Parameters: $r = 1.5$, $K = 50$, $m = 2.5 \times 10^{-5}$.

Figure 9: Illustrates dynamics in Q_1 - P_1 plane, Eq. (67). See Section 3.2.2. Similar to the schematic sketch shown in Fig. 2a. The path from $(0, 0)$ to $(Q_1^*, 0)$ corresponds to the deterministic dynamics for Q_1 , Eq. (49). The path from the quasi-steady state to the fluctuational extinction point $(P_1^*, 0)$ is a straight line. The action S , Eq. (75), is given by the shaded area: $S = Q_1^* P_1^* / 2$.

Figure 10: Results of direct numerical simulations of the stochastic, individual-based model, determining the most likely path to extinction. Shown is the probability distribution of the average number of individuals per occupied patch $\sum_j j f_j / \sum_j f_j$, conditional on the fraction of occupied patches $1 - f_0$. Parameters: $r = 1.5$, $K = 10$, $\delta = 0.103$ (corresponding to $m = 0.028$), $N = 1000$ (**a**) and $r = 1.05$, $K = 10$, $\delta = 0.61$ (corresponding to $m = 0.1342$), and $N = 250$ (**b**). The probability is colour-coded: high probability corresponds to white, low probability to black. How this plot was produced is described in Sec. 3.2.2. Also shown (only in panel **a**) is the result of the slow dynamics given by Eqs. (55), (71), and (73) (solid green line).

Figure 11: Each panel shows the distribution of the number n_j of patches with j individuals, conditional on that there are (n) individuals in the metapopulation. Thus the upper, left-most panel shows n_j conditional on that there is one individual, and the lower right-most panel corresponds to 672 individuals (the expected number of individuals in the steady state). Results from direct simulations (averaged over 10^4 stochastic realisations) (blue) are compared to results of numerical integrations of Eqs. (21,22) (red). Parameters: $r = 1.5$, $K = 10$, $\delta = 0.103$ ($m = 0.028$), $N = 1000$. Note that the first value of j in each panel is $j=1$. In other words, n_0 is not shown.

Figure 12: **(a)** Average time to extinction T_{ext} from direct numerical simulations of the model described in section 2.1, as a function of the number of patches N , for $r = 1.05$, $K = 10$. Symbols ($\times$, $\circ$, $\square$, $\triangle$, ∇) correspond to the following values of δ : 0.0557, 0.128, 0.182, 0.289, 0.611. Each data point corresponds to an average over 100 stochastic realisations. Also shown are numerical fits to the expected behaviour Eq. (74). **(b)** Action as a function of δ . Shown are the limiting result, Eq. (75) (dashed line), as well as the results of the fits shown in the left panel ($\circ$). Error bars correspond to 95% confidence intervals. **(c-d)** Same as top panels, but for $r = 1.5$ and $K = 10$. The symbols ($\times$, $\circ$, $\square$, $\triangle$, ∇ , $\diamond$, $\blacktriangleleft$) correspond to $\delta = 0.04$, 0.064, 0.103, 0.143, 0.222, 0.301, and 0.458. **(e-f)** Same as top panels, but for $r = 1.5$ and $K = 50$. The symbols ($\times$, $\circ$, $\square$, $\triangle$, ∇) correspond to $\delta = 0.066$, 0.173, 0.279, 0.493, and 0.706.

Figure 13: Action S divided by δ^2 according to Eq. (75), in the limit of $\delta \rightarrow 0$, as a function of the carrying capacity K . Solid lines correspond to $r = 1.05$ and 1.5 . Symbols ($\square$, $\circ$, $\diamond$) correspond to the best estimates from Fig. 12a, Fig. 12c, and Fig. 12e.

Figure 14: Average time to extinction, T_{ext} , as a function of the degree of fragmentation K_{tot}/K . See Section 3.2.4. Parameters: $r = 1.01$, $m = 1, 10$, $K_{\text{tot}} = 100, 500, 1000$. Shown are results of Eqs. (C.14,83,84) (solid lines) and results of direct numerical simulations as described in Sec. 3.2.4 for $m = 10$ ($\circ$, $\square$, $\diamond$) and $m = 1$ (∇ , $\triangle$, $\triangleleft$). Error bars correspond to 95% confidence intervals.

Figure 15: Schematic diagram showing relations between different limiting cases of the individual-based stochastic metapopulation model described in section 2.1. The metapopulation consists of N patches coupled by migration. The variables f_j denote the fraction of patches containing j individuals. The parameter m denotes the emigration rate, Eq. (4), and δ characterises how m differs from the critical rate m_c , see Eqs. (35,37) in Sec. 3.1.
